BUNGAY, SUFFOLK.

INDEX.

ABDERHALDEN (PROF. EMIL), Handbuch der biochemischen Arbeitsmethoden, 516
 Abegg (Prof. Richard), Death of, 164; Obituary Notice of, 195
 Abraham (H.), Existence of Two Explosive Potentials, 418
 Abruzzi (S.A.R. Luigi Amedeo di Savoia, duca degli), Esplorazione nei Monti del Karakoram, 469
 Abstract, in the, N. Alliston, 246
 Academies, the International Association of, Prof. Arthur Schuster, F.R.S., 370
 Acoustics: Motion of the Bridge of the Violin, J. W. Giltay and Prof. M. de Haas, 107; New Sound-recording Instrument, Th. Rosset, 479; Damping of Sound by Frothy Liquids, A. Mallock, 545
 Actualités scientifiques, Max de Nansouty, 338
 Adamović (L.), Vegetationsbilder aus Dalmatien, 123
 Adams (J.), a Census Catalogue of Irish Fungi, 149; List of Synonyms of Irish Algæ, 149
 Adams (Lionel E.), Moles and Molehills, 37
 Adams (L. E.), Cause of the Autumnal Epidemic of the Common and the Lesser Shrew, 59
 Adams (W. S.), Displacement of Lines at the Sun's Limb, 46
 Administration and Disease, 226
 Aéro and Motor Boat Exhibition, the International, 79
 Aéronautics: Death of Lieut.-General H. W. L. Moedebeck, 103; the Aërial League and the British Public, 104; Captain Cave Brown Cave, 104; Aërial Navigation of To-day, C. C. Turner, Prof. G. H. Bryan, F.R.S., and E. H. Harper, 132; Flight Velocity, Arnold Samuelson, Prof. G. H. Bryan, F.R.S., and E. H. Harper, 132; the Conquest of the Air, or the Advent of Aërial Navigation, Prof. A. Lawrence Rotch, Prof. G. H. Bryan, F.R.S., and E. H. Harper, 132; Aërodynamik, F. W. Lanchester, Prof. G. H. Bryan, F.R.S., and E. H. Harper, 132; Death of Prof. R. Abegg, 164; Obituary Notice of, 195; Aéronautics, Cantor Lectures at Royal Society of Arts, C. C. Turner, 204; Langley's Contributions to Aéronautics, Dr. Alexander Graham Bell, 263; the Stability and Efficiency of Kites, F. P. Fergusson, 310; W. H. Dines, F.R.S., 310; Wind Statistics and Aéronautics, 432
 Aéroplane Stability, Prof. G. H. Bryan, F.R.S., 10, 69; W. H. Dines, F.R.S., 68
 Africa: die Bienen Afrikas nach dem Stande unserer heutigen Kenntnisse, Dr. H. Friese, 35; Camera Adventures in the African Wilds, being an Account of a Four Months' Expedition in British East Africa for the Purpose of Securing Photographs from Life of the Game, A. Radclyffe Dugmore, Sir H. H. Johnston, G.C.M.G., K.C.B., 429
 Agassiz (Prof. Alexander, For.Mem.R.S.), Death of, 135; Obituary Notice of, Prof. John W. Judd, C.B., F.R.S., 163
 Agassiz (Prof. Alexander), Bequests to Science, 287
 Agriculture: the Fertilising Influence of Sunlight, Dr. E. J. Russell, 6, 249, 489; Dr. John Aitken, F.R.S., 37; F. Fletcher, 156, 488; J. Walter Leather, 277; Fertilising

Effect of Soil Sterilisation, Dr. Bernard Dyer, 96; the Cultivation of Fibre Plants in India, 18; Elements of Agriculture, Prof. G. F. Warren, 31; die Entstehung der Pflugkultur, Dr. Ed. Hahn, A. E. Crawley, 67; the Olive in Cape Colony, 77; Nitrogen-fixing Bacteria and Non-leguminous Plants, Prof. W. B. Bottomley, 96; Forecast for the Wheat Crop of South Australia, 106; Hybridisation of Wheat in Cape Colony, 138; Milk Records for the Dairy Herd at the Rosslynlee Asylum, Dr. Lauder and Mr. Fagan, 167; the Sugar Industry in Hawaii, 172; Agricultural Seeds and their Weed Impurities, Prof. T. Johnson and Miss R. Hensman, 179; Sisal in British East Africa, 199; Nitrogen-content of Sawdust, Mr. Kinch, 199; Usefulness of the Bee in Connection with Agriculture, W. Herrod, 199; Death of Prof. Julius Kuehn, 227; Obituary Notice of, 256; Annual Report for 1909 of the Rothamsted Experimental Station, 258; Results of Trials at Rothamsted on the New Nitrogenous Fertilisers, Cyanamide and Calcium Nitrate, A. D. Hall, 382; Opening of the New School of Agriculture, Cambridge, 260; International Congresses on Ornithology and Tropical Agriculture, 260; International Congress on Tropical Agriculture and Colonial Development, 444; the Principles of Soil Management, Profs. T. Lyttleton Lyon and E. O. Fippin, 272; Report on the Poultry Industry in Belgium, Edward Brown, 275; Report on Insect Pests in the West Indies, 288; West of Scotland Agricultural College, Reports on Experiments, 313; Durham County Council Education Committee, Report of Dairy Investigations, 313; Northumberland Education Committee, Guide to Experiments for 1909, East Sussex Education Committee, Experiments on Meadow Hay, 313; Agricultural Students' Gazette, Experiments on Pasture, 313; Journal of the Department of Agriculture and Technical Instruction for Ireland, 313; Destructive Insects and Pests Acts, 346; Composition of Indian Rice, David Hooper, 347; Experiments of the Royal Agricultural College, Cirencester, 382; Report on the Progress of Agriculture in India for 1907-9, 352; Wheat in India, Mr. Howard, 352; Mycological Work, Dr. Butler, 352; Indigo, Mr. Bergtheil, 353; Vanilla-growing in the West Indies, 408; Ooze and Irrigation, Rev. Hilderic Friend, 427, 489; Struggle for Water between Living Organisms and Natural Media, A. Müntz, 449; Locusts in South Africa, 466; Application of Science to Agriculture in the West Indies, 498; Agricultural Research, 507; Butter Regulations, G. Brownlee, 531; Experiments on Sugar-cane, 531; Methods of Picking, Drying, and Packing Hops in Kent, Arthur Amos, 532; Experiments on Manuring, 533
 Aitken (Dr. John, F.R.S.), the Fertilising Influence of Sunlight, 37; Practice and Knowledge, 70
 Aitken (Prof.), Observations of Satellites, 140
 Albino Hair, Certain Reactions of, Igerna B. J. Sollas, 96; Geo. P. Mudge, 188
 Albrecht (Dr.), Comet 1910a, 79; Stars with Variable Radial Velocities, 140
 Alcyonarians, an Account of the, Collected by the Royal

- Indian Marine Survey Ship *Investigator* in the Indian Ocean, Prof. J. Arthur Thomson, J. J. Simpson, and Dr. W. D. Henderson, 483
- Aldred Lecture at Society of Arts, Halley and his Comet, Prof. H. H. Turner, F.R.S., 387
- Aldren-Turner (Dr. W.), a Text-book of Nervous Diseases, 337
- Alexander (Lieut. Boyd), Death and Obituary Notice of, 380
- Alexandra (Queen), Union Jack presented to Captain Scott by, 530
- Algebra: a New Algebra, S. Barnard and J. M. Child, 4; College Algebra, Dr. S. C. Davisson, 4
- Allbridge (T. J.), a Transformed Colony, Sierra Leone as it was and as it is, its Progress, Peoples, Native Customs, and Undeveloped Wealth, 523
- Allen (Dr. E. J.), Cultivation of Diatoms as Food to be used in the Rearing of Various Types of Marine Larvæ, 257
- Allen (Prof. Frank), Colour-blindness, 69
- Allen (Dr. F. J.), the Comets (1910a and Halley's), 108
- Allen (Dr.), Maya Codices, 288
- Allen's Commercial Organic Analysis, 456
- Alliston (N.), in the Abstract, 246
- Alloys Research Committee of the Institution of Mechanical Engineers, Ninth Report to the, the Properties of some Alloys of Copper, Aluminium, and Manganese, Dr. Walter Rosenhain and F. C. A. H. Lantsberry, 140
- Alloys, Light, Dr. Walter Rosenhain, 461
- Alt (Dr. E.), Distribution of Thunderstorm Frequency in Central and Northern Europe, 77
- Ameghino (Dr. Florentino), Young Tapir-skull from Tucuman, 198; Alleged Human Origin of the "Burnt Earths" of Argentina, 257
- America: Proposed National Bureau of Seismology, 227
- American Association for Advancement of Science: a Geologic Forecast of the Future Opportunities of Our Race, Prof. T. C. Chamberlin, 50; Boston Meeting of the, 113; the Teaching of Physics, Prof. K. E. Guthe, 113; the Study of Solutions, Prof. Louis Kahlenberg, 113; Engineering as a Profession, Prof. G. F. Swain, 114; the Principles of Palæogeography, Prof. Bailey Willis, 114; Evolution of Intelligence, Prof. C. Judson Herrick, 114; Response to Chemical Stimulation, Prof. H. M. Richards, 115; Racial Differences in Mental Traits, Prof. R. S. Woodworth, 115; Chemical Regulation of the Processes of the Body, Prof. W. H. Howell, 116; Method and Matter of Science, Prof. John Dewey, 116
- American Economic Entomology, 47
- American Invertebrates, Papers on, 234
- American Philosophical Society, the, 504
- Amos (Arthur), Methods of Picking, Drying, and Packing Hops in Kent, 532
- Amperemeter, a New, 413
- Amundsen's (Captain) Expedition, 435
- Anæsthetics, the Administration of, 295
- Anatomy: Death of Prof. W. Krause, 15; History of the Human Body, Prof. H. H. Wilder, 214; Death of Edouard van Beneden, 286, 329; Obituary Notice of, 344; Voordrachten over den Bouw van het centrale Zenuwstelsel—een Voorbereiding tot de Kliniek der Zenuwziekten, Door Prof. J. W. Langelaan, 308; the Anatomy of the Common Squid, *Loligo pealii*, L. W. Williams, 366; Death of Prof. Emil Zuckerkandl, 406
- Ancient Angling Authors, W. J. Turrell, 155
- Anderson (J. A.), Method of Testing Screws, 107
- Anderson (Knud), African Fruit-bats of the *Epomophorus* Group, 17
- Anderson (Dr. Tempest), Volcano of Matavanu in Savaii, 269
- Andrade (E. N. da C.), Viscous Flow in Metals, 237
- André (Ch.), Effects produced on Hail Storms by the Hail Cannon, 209
- André (M.), Observations of Halley's Comet, 410
- Andrewes (Dr.), Bacteria of Sewer Air, 22
- Angling: Minor Tactics of the Chalk Stream and Kindred Studies, G. E. M. Skues, 394
- Angot (Alfred), Observations of Halley's Comet, 410; Magnetic and Electric Variations on the Nights of May 18 and 19, 1910, 419
- Ångström (Prof. K. J.), Death of, 74; Obituary Notice of, Prof. Arthur Schuster, F.R.S., 132
- Animal Life, Altruism in, J. H. Elgie, 489
- Antarctica: Scientific Work Accomplished by Dr. Charcot's Recent Antarctic Expedition, 16; Forthcoming German Antarctic Expedition, 41; Projected German Antarctic Expedition, 318; Dr. Penck and Antarctic Expeditions, 75; the Proposed Scottish National Antarctic Expedition of 1911, 101; National Geographic Society's Gold Medal presented to Sir Ernest Shackleton, 135; Scientific Work of the British Antarctic Expedition of 1907-9, J. Murray, 149; British Antarctic Expedition, Start of the *Terra Nova*, 404; Union Jack presented to Captain Scott by Queen Alexandra, 530; Antarctic Geology, Prof. W. M. Davis, 505
- Anthropology: Notes on High Albania, Miss M. E. Durham, 29; Royal Anthropological Institute, 29, 88, 298, 547; Egyptian Antiquities and Customs, A. M. Blackman, 42; Modes of establishing Fictitious Kinship now Current in the Panjab, H. A. Rose, 76; the Evolution of Man in the Light of Recent Investigations, Prof. W. J. Sollas, 88; the Gibraltar Skull, Dr. A. Keith, 88; Racial Differences in Mental Traits, Prof. R. S. Woodworth, 115; Infantilism and Idiocy, and Gigantism and Idiocy, Dr. A. Marie, 137; the Andaman Islands, A. R. Brown, 147; Skulls from a Primitive Cemetery, Prince Georges Cantacuzene, 197; Skulls discovered by M. Mansuy in the Cave at Pho-Binh-Gia, Dr. R. Verneau, 197; Origin and Distribution of the Cross-bow in India, O. Forrest, 228; Mr. Thurston, 228; les Groupes de Civilisation en Scandinavie a l'Époque des Sépultures à Galerie, Dr. Knut Stjerna, 228; Alleged Human Origin of the "Burnt Earths" of Argentina, Dr. Florentino Ameghino, 257; Native African Art, 286; Certain Sacred Stones used in Burial and other Rites by the Aborigines of Australia, R. H. Mathews, 287; Maya Codices, Drs. Tozzer and Allen, 288; les Sôfs chez les Abadites, Dr. J. Huguet, 345; New Guinea Pygmies, Dr. A. C. Haddon, F.R.S., 433; Dr. A. B. Meyer, 498; Native Decorative Art in Nigeria, N. W. Thomas, 436; the Term Rom or Romani applied to the Gypsy Race, Leo Winer, 436; "The Fight for the Cows" in the Rigveda, A. C. Sen, 450; (1) Craniological Observations on the Lengths, Breadths, and Heights of 100 Australian Aboriginal Crania; (2) Biometrical Study of the Relative Degree of Purity of Race of the Tasmanian, Australian, and Papuan; (3) the Place in Nature of the Tasmanian Aboriginal as deduced from a Study of his Cranium, Prof. R. J. A. Berry, Dr. A. W. D. Robertson, and K. S. Cross, 479; Curious Wooden Engraved Blocks used by the Bushongo of the Belgian Congo, T. M. Joyce, 531; Rain-making Chiefs, W. E. Cole, 531; the Ekoi of Southern Nigeria, P. A. Talbot, 547
- Antlitz der Erde, das, Prof. E. Suess, Prof. J. W. Gregory, F.R.S., 451
- Ants, their Structure, Development, and Behaviour, Prof. W. M. Wheeler, Right Hon. Lord Avebury, F.R.S., 515
- Antwerp, the Astronomical Society of, 409
- Apiculture: How to Keep Bees for Profit, Dr. D. E. Lyon, F. W. L. Sladen, 519
- April Meteor Showers, John R. Henry, 189
- April Shooting Stars, Mr. Denning, 201
- Arber (E. A. Newell), Fossil Plants from Newfoundland, 59
- Archæology: Vestigia di una Città Ellenica arcaica in Creta, Dr. Luigi Pernier, 105; the Stone and Bronze Ages in Italy and Sicily, T. Eric Peet, 122; the "Reindeer" from the Lorthet Grotto, Dr. Henry O. Forbes, 125; Mr. Myring's Recent Discoveries of Prehistoric Pottery in Peru, Sir W. H. Bailey, 148; Explorations in Turkestan, Expedition of 1904, Prehistoric Civilisations of Anau, L. W. King, 157; the Tomb of Queen Tiyi, 227; the Roman Fort at Manchester, 225; Excavations at Toothill and Melandra, 225; Areika, R. Randall Maciver and C. Leonard Woolley, H. R. Hall, 251; the British Camp at Wallington, N. F. Robarts and H. C. Collyer, 298; Proposed Excavation of Verulam, 345; Paintings and Engravings found in the Caves of the Pyrenees, l'Abbé H. Breuil, 346; Excavation of the Lake Village at Meare, 379; Catalogue of Bronzes, &c., in Field Museum of Natural History, Reproduced from Originals in the National Museum of Naples, Prof. F. B.

- Tarbell, 396; Crète the Forerunner of Greece, C. H. Hawes and Harriet Boyd Hawes, 422; Discovery at Bay of Islands of a Series of Engraved Rocks, C. L. Wragge, 436; the Annual of the British School at Athens, H. R. Hall, 462; Shell-mound at Ellis Landing, N. C. Nelson, 465; Discovery of a Burial Cave, probably Neolithic, at Montouliers, Lucien Mayet and Laurent Maurette, 514
- Archenhold (Herr), Halley's Comet, 439
- Architecture: National Monument to Victor Emanuel, 380; Who Planned the Taj? Rev. H. Hosten, 450
- Architecture, Naval: Launch of H.M.S. *Colossus*, 231; see Naval Architecture
- Arctica: Croisière Oceanographique accomplie a bord de la *Belgica* dans la Mer du Grönland, 1905, Duc d'Orléans, Dr. William S. Bruce, 8; Cooperation in Magnetic Work, 41; Proposed Arctic Zeppelin Airship Expedition, 41; Expedition to Investigate the Possibilities of an Airship Flight to the North Pole, 164; the North Polar Question, 76; the Siege and Conquest of the North Pole, George Bryce, 366; Commander Peary's Expedition to the North Pole, 283; Captain Amundsen's Expedition, 435
- Ardern (Edward), the Disinfection of Sewage and Sewage Filter Effluents, with a Chapter on the Putrescibility and Stability of Sewage Effluents, E. B. Phelps, 411
- Areika, R. Randall Maciver and C. Leonard Woolley, H. R. Hall, 251
- Armit (Dr. H. W.), an Investigation into the Mechanism of Production of Blackwater Fever, Dr. J. O. Wakelin Barratt and Dr. Warrington Yorke, 83
- Armstrong (Dr. E. Frankland), the Simple Carbohydrates and Glucosides, 333; Origin of Osmotic Effects, iii., the Function of Hormones in stimulating Enzyme Change in Relation to Narcosis and the Phenomena of Degenerative and Regenerative Change in Living Structures, 446
- Armstrong (Prof. H. E.), Origin of Osmotic Effects, iii., the Function of Hormones in Stimulating Enzyme Change in Relation to Narcosis and the Phenomena of Degenerative and Regenerative Change in Living Structures, 446
- Arnaud (A.), Isomerisation of Oleic Acid by the Displacement of the Double Linkage, 480
- Arnold (Prof. J. O.), Uniform Nomenclature of Iron and Steel, 326
- Arnoux (René), Longitudinal Equilibrium and Curvature of the Carrying Surfaces of Aeroplanes, 209
- Artropodos Parásitos, Prof. Daniel Greenway, 426
- Asiatic Society of Bengal, Calcutta, 149, 330, 450
- Assmann (Mr.), Proposed Meteorological Observations during Progress through the Tail of Halley's Comet, 320
- Association of Technical Institutions, the Organisation of Technical Education, Dr. R. T. Glazebrook, F.R.S., 83
- Association of Teachers in Technical Institutions, a National System of Technical Education, Dr. Robert Pohl at, 206
- Astronomy: Astronomical Occurrences in March, 19; in April, 140; in May, 259; in June, 439; Comet 1910a, M. Esclanton, 19; J. Comas Sola, 19; Mr. Innes, 45; M. Quénnisset, 79; Comte de la Baume Pluvinel, 79; Dr. Wright, 79; Dr. Albrecht, 79; Messrs. Merrill and Oliver, 70; Prof. Barnard, 79; Dr. Kobold, 79, 108, 383; Herr Pechüle, 79, 260; Michie Smith, 108; Mr. Evershed, 108; Herr Konkoly, 108; Dr. F. J. Allen, 108; Knox Shaw, 169; Dr. Ristenpart, 201; Herr Castro, 201; Herr Tscherny, 260; Prof. Stroobant, 260; Spectrum of the Comet 1910a, H. Deslandres and P. Idراع, 119, 140; Colour of Comet 1910a during its Perihelion Passage, Mr. Innes, 534; Our Astronomical Column, 19, 45, 79, 108, 140, 169, 201, 231, 259, 290, 320, 348, 383, 409, 439, 468, 501, 533; Fireball of February 17, W. F. Denning, 20; Pidoux's Comet 1910b, 20, 79; a Naked-eye Sun-spot Group, J. H. Elgie, 20; Halley's Comet, 20; W. B. Broderick, 46; Mr. Olivier, 79; Dr. F. J. Allen, 108; G. Renaudot, 119; Knox Shaw, 169, 409; Jean Mascart, 169, 471; Dr. Ebelle, 201, 386, 410; M. Baldet, 201, 224; Dr. Smart, 223, 322; C. E. Guillaume, 224, 470; M. Flammarion, 225; Dr. Ristenpart, 259; Mr. Ryves, 259; Mr. Innes, 259, 386, 534; M. Giacobini, 259, 299, 386, 470, 479; Mr. Denning, 260; C. Leach, 277, 321, 348, 384, 410, 471; W. B. Tripp, 290; Sir Robert Ball, 290; Dr. H. N. Russell, 290; J. Holetschek, 291, 348; Gustave Gilman, 321, 348; Dr. A. C. Jordan, 321; Mr. Gruning, 321; Mr. Bellamy, 321; Mr. Crommelin, 321; Dr. Pio Emanuelli, 321; Prof. Attilio Sesta, 348; J. Franz, 348; Dr. Wright, 349; Prof. Frost and Dr. Slocum, 349; M. Coggia, 359, 386; Dr. F. Iniguez, 384; Prof. Michie Smith, 384; Prof. Dyson, 385; Rev. Dr. A. Irving, 385; Prof. Birkeland, 385; E. Clegg, 386; W. E. Rolston, 386; MM. Bernard and Idراع, 386; V. M. Slipher and Mr. Lampland, 386; Mr. Evershed, 386; M. Esclanton, 409; M. Borrelly, 410; Prof. George Forbes, 410; G. W. Grabham, 410; M. Eginitis, 410, 439; M. André, 410; Georges Claude, 410; MM. Angot, Lebel, Limb, and Nanty, 410; Langton Cole, 439; Dr. Franz, 439; Dr. Wolf, 439; Prof. Franz, 439; Prof. Sykora, 439; Prof. Donitch, 439; Herr Archenhold, 439; Dr. Hartmann, 439; E. Marchand, 439; M. Popoff, 439; J. Baillaud and G. Demetresco, 439; Prof. Max Wolf, 470; Dr. Cerulli, 470; A. Miethe, 470; Herr Osthoff, 470; Dr. Banschewicz, 470; M. Luizet, 470; MM. Cirera and Ubach, 470; J. Comas Sola, 470, 479, 534; J. W. Scholes, 471; H. E. Wood, 534; W. M. Worsell, 534; H. C. Reeve, 534; Mr. Finlay and Prof. Rudge, 534; Halley's Comet in Japanese Records, K. Hirayama, 140; Halley's Comet as seen in 1835 compared with Donati's in 1858, A. Brothers, 148; Transit of Halley's Comet across Venus and the Earth in May, Prof. Kr. Birkeland, 217; Observations of Halley's Comet and Venus, E. T. Mullens, 339; Cardboard Model showing the Relative Positions of Halley's Comet, the Sun, and the Earth during Present Apparition, Rupert Hicks, 230; Halley's Comet, its History, with that of other Noted Comets, and other Astronomical Phenomena, Superstitions, &c., Rev. John Brown, 276; Halley's Comet and Meteorology, 320; Proposed Meteorological Observations during Progress through the Tail of Halley's Comet, Prof. Hergesell, 320; Messrs. Assmann and Teisserenc de Bort, 320; Meteorological Observations during the Passage of the Earth through the Tail of Halley's Comet, W. H. Dines, F.R.S., 427; J. N. Pring, 427; Meteors from Halley's Comet, Mr. Denning, 320; Changes in Halley's Comet, Ernest Esclanton, 330; Halley's Comet and Magnetic and Electrical Phenomena, Dr. C. Chree, F.R.S., 367; Halley's Observations on Halley's Comet, 1682, A. S. Eddington, 372; Halley and his Comet, Aldred Lecture at Society of Arts, Prof. H. H. Turner, F.R.S., 387; Composition of the Atmosphere after the Passage of Halley's Comet, Georges Claude, 419; Observations of Halley's Comet made at the Observatory of Athens, D. Eginitis, 449; Phenomena Observed at the Pic du Midi on May 18-19, Émile Marchand, 449; the Tail of Halley's Comet on May 18-19, Howard Payn, 487; W. H. Finlay and W. A. Douglas Rudge, 487; the Transit and Tail of Halley's Comet, Knox Shaw, 501; Dr. Meyermann, 501; Father S. Chevalier, 502; M. Marchand, 502; MM. Cirera and Pericas, 502; M. Eginitis, 502; J. Baillaud and M. Boinot, 502; Dr. Rambaut, 502; H. H. Grunning, 502; L. Whitaker, 502; Observations on Halley's Comet made at the Observatory of Ebra, Spain, MM. Cirera and Pericas, 513; Change in the Nucleus of Halley's Comet, J. Baillaud and A. Boinot, 513; New Canals on the Planet Mars, Percival Lowell, 29; Occultation of Mars, April 13, 169; Occultation of Mars by the Moon on April 13, Dr. W. Krebs, 383; Mars during the Recent Opposition, W. E. Rolston, 440; the New Canals on Mars, M. Jonckheere, 468; the Intrinsic Brightness of the Sun, Charles Nordmann, 29; the Intrinsic Brilliance of the Sun, Dr. Nordmann, 232; Astronomical Curiosities, Facts and Fallacies, J. Ellard Gore, 33; Curiosities of the Sky, Garrett P. Serviss, 33; Death of D. O. Mills, 41; Brilliant Fireball of February 27, W. F. Denning, 45; the Sun-spots of September 25, 1909, Dr. Slocum, 46; Displacement of Lines at the Sun's Limb, W. S. Adams, 46; the "Anuario" of the Madrid Observatory, 1910, 46; Accelerated Velocity of Jupiter's Red Spot Hollow, Scriven Bolton, 70; the Flattening of Io, First Satellite of Jupiter, J. Comas Sola, 389; the Lacings between Jupiter's Belts, Prof. Lowell, 501; the Phenomenon of Purkinje, Ch. Gallissot, 90; Some Scientific Centres, XV., the Mount Wilson Solar Observatory of the

- Carnegie Institution of Washington, Prof. G. E. Hale, Prof. H. H. Turner, F.R.S., 97; the Solar Eclipse of 1912 April 17, M. D. NATURE

A WEEKLY ILLUSTRATED JOURNAL OF SCIENCE.

"To the solid ground
Of Nature trusts the mind which builds for aye."—WORDSWORTH.

THURSDAY, MARCH 3, 1910.

AN ENCYCLOPÆDIC TREATISE ON THE PROTOZOA.

Lehrbuch der Protozoenkunde. Zweite Auflage der "Protozoen als Parasiten und Krankheitserreger." By Dr. F. Doflein. Pp. x+914; 825 figures. (Jena: Gustav Fischer, 1909.) Price 24 marks (unbound).

THE study of the Protozoa has made very great progress during the last twenty years, so great that even those who devote themselves to this branch of knowledge have the utmost difficulty in keeping pace with its rapid advance. This state of things is due chiefly to the great practical importance of the Protozoa for medical, veterinary, and agricultural science, but also because the primitive forms of life give the clue to many biological problems of fundamental importance. Hence the number of those who occupy themselves with researches upon Protozoa has very much increased, both amongst professed zoologists and also amongst those to whom zoological questions are a secondary consideration; all such workers, however, whatever their aims, will welcome the publication of Prof. Doflein's treatise. This work is ostensibly the second edition of his well-known manual on the Protozoa as parasites and causes of disease, a most useful book in its time, though now a little behind by the flowing tide of research; its parentage, however, is scarcely recognisable, since the second edition appears with new title, changed form, and greatly enlarged scope. The treatment of parasites and disease, though not neglected, takes a secondary place, and the work has become an extensive general treatise on the Protozoa.

It is difficult, within the limits of space imposed upon a reviewer, to give an adequate account of the wealth of facts, ideas, and illustrations contained in the 900 or so pages of this book. The work is divided into two halves, the first containing a general account of the natural history of the Protozoa, the second a more detailed systematic description of the groups of Protozoa and of the special problems connected with them.

The general part begins with a short introduction giving the definition and distinctive characters of the Protozoa, and is then subdivided under the headings morphology, physiology, reproduction, biology (or bionomics), system, and technique. The Protozoa are regarded as unicellular organisms occupying a middle position between the Bacteria and their allies below and the Metazoa above. As regards the structure of protoplasm, the author is a strong adherent of the alveolar theory of Bütschli. The nucleus of Protozoa is described in detail, both as regards constitution and morphology, and special sections are devoted to chromidia, centrosomes, and blepharoplasts; we miss, however, any discussion of the binuclear hypothesis of the cell, put forward by Hartmann and Prowazek, in relation to the theory of the centrosome. The term "blepharoplast" is applied by the author to the kinetonucleus of trypanosomes, as is usual in Germany; we must confess to a feeling of surprise, however, that the author doubts the nuclear nature of this body.

The section on physiology is subdivided under the headings "Stoffwechsel" and "Kraftwechsel." The section on reproduction deals with fission, fertilisation, form and development, the Protozoa as unicellular organisms, and theoretical problems of sex and reproduction. Under the fifth of these headings the author discusses the hypothesis of nuclear dualism (more correctly dualism of the chromatin-substance) of the protozoan organism put forward by Schaudinn and Goldschmidt; according to this view, every protozoon is regarded as containing two nuclei (or rather two kinds of chromatin), a "Stoffwechselkern" of vegetative somatochromatin, and a "Geschlechtskern" of generative idiochromatin. The author considers (and we fully agree) that there are not two distinct kinds of nuclear substance, but that one and the same substance is responsible both for functional activity and for heredity in the protozoan body; he quotes Hertwig's opinion in support of his own, to the effect that somatochromatin is idiochromatin of which the activities are awakened, and idiochromatin is somatochromatin in which the activity is dormant but can be renewed under suitable conditions. He considers,

further, that many substances, which have been mistaken for chromatin on account of their affinity for stains, are in reality reserve materials, precipitation-products, and the like, and that this confusion of chromatin with other substances has often led to the erroneous distinction of two kinds of chromatin.

In discussing the theoretical aspects of reproduction and fertilisation, the author states and reviews in a very clear and interesting manner the various theories that have been put forward, especially those of Weismann, Bütschli, Hertwig, and Schaudinn, and ends by sketching in brief outline a theory of his own. Living cells are regarded as consisting principally of two groups of vitally-active substances, the one, more fluid, responsible for motor phenomena, the other, more viscid, regulating metabolic cell-functions. In cell-reproduction by fission these substances are never distributed with mathematical equality amongst the descendants, hence continued division brings about accumulations of different properties in certain individuals, with, as a consequence, impaired vital activity and reproductive power. Individuals are produced, some of which become richer in reserve material (female), others in motile substance (male). Since these two kinds of individuals contain aggregations of substances which have intense mutual chemical reactions, they exert an attraction one towards the other; the two individuals tend to unite as gametes, and by their union cell-equilibrium is restored and vital powers renewed. Hence fertilisation is regarded as a necessity for the life-cycle, due primarily to the imperfections of cell-division and to the consequent loss of equilibrium in the cell-constituents, a view which unites and extends the theories of Schaudinn and Hertwig respectively.

The section dealing with the bionomics of the Protozoa is divided into the following subsections:— occurrence and distribution, habit and mode of life, adaptation of the methods of nutrition, adaptations of the reproductive processes and means of dispersal, influence of the medium, light and rays, temperature and climate. Under the heading "System," the various classifications that have been put forward are discussed. The Protozoa are classified into two main divisions, first, the Plasmodroma, including the Rhizopoda, Mastigophora, and Sporozoa; and, secondly, the Ciliophora, including the Ciliata and Suctoria. The Spirochætes are regarded as leading from the organisms of bacterial nature to Mastigophora, and hence, for the first time, we believe, in a treatise on Protozoa, the Mastigophora are dealt with before the Rhizopoda.

The section on technique is a brief summary of methods of cultivating, investigating, and preserving Protozoa.

The special part of the work is a detailed description, in systematic order, of the structure and life-histories of the orders, families, and more important genera and species of Protozoa. Intercalated amongst the systematic descriptions are sections dealing with the parasitic and pathogenic importance of certain groups, namely, the Spirochætes, Flagellates, Amœbæ, and Telosporidia. In these sections the diseases produced by the Protozoa in question, and

their pathology and etiology, are discussed, with figures and descriptions of the blood-sucking invertebrates which are responsible for their dissemination. From all this wealth of material we must be content to note a few points concerning debated questions. The theory of an alternation of sexual and non-sexual generations in trypanosomes, comparable to the alternating cycles of Hæmosporidia, is regarded as purely hypothetical and in need of proof. The author considers that it will probably be necessary in the future to place the genus *Trypanosoma* in the family Cercomonadidæ, in close proximity to *Herpetomonas* and *Crithidia*; on the other hand, *Trypanoplasma* is placed in a separate family, Bodonidæ. Schaudinn's statements with regard to the relationship of *Trypanosoma* to *Hæmoproteus* and *Leucocytozoon* are set forth in detail, together with the criticisms and objections of Novy, MacNeal, and others; judgment is suspended until more exact information shall have been obtained, but Hartmann's union of Hæmosporidia and Trypanosomes into one group, the Binucleata, is not accepted. The genus *Hæmoproteus* (*Halteridium*) is dealt with in an appendix to the Hæmosporidia, together with *Babesia*, *Endotrypanum*, and *Leishmania*; it will be a surprise to most protozoologists to meet with *Leishmania* in this company, and we are decidedly of opinion that its proper position is in the neighbourhood of *Herpetomonas*.

In the class Rhizopoda the forms with lobose pseudopodia and a shell are placed with the monothalamous Foraminifera, so that this order can no longer be defined by the reticulate nature of its pseudopodia. The Protomyxidea, including the genera *Vampyrella*, *Pseudospora*, *Chlamydomyxa*, and *Labyrinthula*, are placed as an appendix of uncertain position at the end of the Rhizopoda.

The Telosporidia are subdivided into Gregarinidæ and Coccidiomorpha; the second of these divisions includes the Coccidia and the Hæmosporidia, which are divided into Plasmodidæ and Hæmogregarinidæ. We regret to see the familiar generic name *Coccidium* replaced by *Eimeria*; this is one of those many cases where, in our opinion, rebellion against the law of priority in nomenclature is not only lawful but imperative.

The feeling aroused by even a cursory scrutiny of this book is one of dismay at the vast extent to which the subject has grown, astonishment at the erudition of the author, and gratitude to him for his painstaking diligence in putting together such a store of important facts and so useful a guide to the intricacies of the subject. It would not be difficult, perhaps, to point out parts of the book here and there in which certain subjects or groups have not been so well treated as others; the Hæmogregarines, for instance, are not dealt with very adequately. But a treatise of this size, on which the carping critic would be perforce silent, could hardly have been written by a human being, or even by several. It is seldom that so great a work is completed by one man at the present time. A striking feature of the book is the number of beautiful illustrations, and especially of previously unpublished figures, some by the author and some by other investigators; in particular we

would direct attention to many figures reproduced from those left behind by the late Dr. Fritz Schaudinn, which will be of the greatest interest to all protozoologists.

In conclusion, we have no hesitation in recommending this work to all those who wish to possess an admirable and exhaustive treatise on the Protozoa.

E. A. MINCHIN.

THE EARLY HISTORY OF NEW ZEALAND. *Murihiku, a History of the South Island of New Zealand and the Islands adjacent and lying to the South, from 1642 to 1835.* By Robert McNab. Pp. xv+499; with plates and charts. (Wellington, N.Z.: Whitcombe and Tombs, Ltd., 1909.)

THOSE who are personally acquainted with that prosperous and very up-to-date portion of His Majesty's Empire now known as the Dominion of New Zealand will find it difficult to realise that so recently as the year 1835 the Customs House authorities in London decided that whale oil imported from that country was liable to a duty of 26l. 12s. per tun, on the ground that it did not come from a British possession. So many stirring events, however, had already taken place in New Zealand at this date that it has required eleven years of research to enable Mr. McNab to recover from the "forgotten past" the materials for a history of the southern portion of the Dominion from the time of its discovery by Tasman in 1642 up to the year mentioned. The task has been an arduous one, involving the close study of rare works in English, Spanish, French, and Russian, and the examination of countless official documents and files of local newspapers. Information has been brought together from every quarter of the globe, and not the least interesting of the author's discoveries is that of a series of manuscript logs of early voyages, which he found in the library of the Essex Institute at Salem, Massachusetts.

The classical explorations of Tasman, Cook, and Vancouver are already familiar to students of history, but the details of Bellingshausen's visit have hitherto been almost unknown to English readers. He commanded a Russian expedition which reached New Zealand in 1820. The narrative of the voyage, published in Russian, is now very rare. An abridged translation was published in German in 1904, and Mr. McNab has included in the present volume an English translation of the portions relating to New Zealand, the most interesting of which is a graphic account of the sea-elephant fishery which then flourished in Macquarie Island.

In the early part of the nineteenth century New Zealand and the adjacent islands were a kind of no-man's-land, and a happy hunting-ground for sealers and whalers from Australia and America. The records of these early trading expeditions, culled largely from the shipping reports and correspondence columns of the Sydney newspapers, contain much of thrilling adventure. The men must have been made of stern stuff who would consent to be left behind in small sealing gangs on an almost unknown coast, exposed to the attacks of the cannibal Maoris—attacks which were sometimes very successful—and with

scanty supplies, while their ship continued her explorations, to call for them and their sealskins at some future date, often many months later. Sydney formed the headquarters of most of these expeditions. It was then a convict settlement, and we are told that Governor Phillip actually asked the English authorities for special powers to deport condemned men to New Zealand to be handed over as food for the natives!

The compilation of this work has evidently been a labour of love, but the author has none the less earned our gratitude by the manner in which he has fulfilled his task. Ethnologists and naturalists will both find a good deal to interest them in the book, but it is as a piece of historical research that it must be judged, and we expect that the writer of historical romance, as well as the more serious student of history, will profit largely by it in years to come.

A. D.

CHEMICAL CONTROL OF FOODSTUFFS.

Food Inspection and Analysis. For the use of Public Analysts, Health Officers, Sanitary Chemists, and Food Economists. By Albert E. Leach. Pp. xviii+954+xl plates. Second edition, revised and enlarged. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1909.) Price 31s. 6d. net.

THIS work, the first edition of which was reviewed in these columns some four years ago (*NATURE*, November 17, 1904, p. 57), is favourably known in this country as a very useful aid in the analysis of foodstuffs. For the information of readers interested in this subject and hitherto unacquainted with the volume, we may mention that it aims at giving, in a compass of about a thousand pages, a short description of the origin and composition of all the chief foods, condiments, and alcoholic beverages; together with a selection of the most approved methods for their chemical and physical examination.

General laboratory equipment is dealt with, and there are sections devoted to special apparatus, such as the microscope, camera, tintometer, refractometer, and polarimeter. Numerous tables of analytical constants are provided, as well as many illustrations of microscopical structure; in fact, the idea appears to be to make the book so far as possible self-sufficient for all ordinary work. The convenience of this is obvious; the essential information, enabling routine samples to be disposed of, is collected in one volume instead of being scattered over half-a-dozen. For assistance in dealing with special cases, where fuller details are necessary, a long list of references is appended to each chapter.

The new matter in the second edition runs to some 167 pages. A notable extension is made in the chapter devoted to cereals. Here we remark the inclusion of such matters as the use of pancreatin for starch-converting purposes alternatively to malt extract; a table (Kröber's) for determining pentoses and pentosans from the amount of phloroglucide; a scheme for complete ash-analysis, and sections dealing with the bleaching and examination of flour. These last, in addition to the usual methods for determining the proportions of gluten, gliadin, and other proximate

constituents of flour, include descriptions of baking-tests, absorption and dough-tests, and the two best-known means of recognising bleached flour, namely, extraction of the colouring matters with light petroleum, and the detection of nitrites in the sample.

An extension which will be found very useful is a separate chapter upon the examination of flavouring-extracts and their substitutes. Processes are given for the determination of vanillin, coumarin, benzaldehyde, lemon oil, wintergreen oil, and other essential oils occurring in extracts and essences; and notes upon adulterants and imitations are also included.

It will be readily understood that with so large a field to cover a single volume does not, even with a thousand pages, suffice for any exhaustive discussion of the various topics. The really difficult cases of adulteration, the doubtful "border-line" problems, remain always dependent for their solution upon the experience, skill, and wider knowledge possessed by the analyst. Beyond this general observation, however, there is little but praise to bestow upon the book. Apart from one or two misprints, the only questionable matter noticed is the Defren's table on pp. 595-7, where the values of lactose appear rather doubtful; and one may claim a little grumble at the pounds avoirdupois; the book is not, in the literal sense, likely to be a *vade mecum*. It will lie on the laboratory table, but it will be worth its place there. C. S.

THE MOVEMENTS OF CHROMATOPHORES IN PLANTS.

Die Gestalts- und Lageveränderung der Pflanzen-Chromatophoren. By Dr. Gustav Senn. Pp. xv + 397. (Leipzig: W. Engelmann, 1908.) Price 20 marks.

CHROMATOPHORES in plants were for long regarded as merely temporarily differentiated fragments of the cytoplasm, and, even within the present decade, were viewed as cell-organs the physiological behaviour of which is largely or mainly determined by the general protoplasm; but more recent investigations have increasingly led botanists to regard chromatophores, not only as morphological individuals—so to speak—within the cell, but also as physiological organisms in the energid. The climax of this view is the suggestion that chromatophores are in phylogeny nothing more than descendants of parasitic green organisms which entered into symbiosis with cells not possessing chlorophyll. Though this extreme hypothesis is not favoured by Dr. Senn, the evidence which he supplies causes him to conclude that chromatophores have larger powers of active contractility and more varied irritability than has hitherto been believed. He concludes that their change of shape and movements in the cell are exclusively or mainly the result of their own special activity, and that they are not passively distorted or transported by the cytoplasm (though he naturally admits their passive carriage by rotating protoplasm and the like).

The book begins with the consideration of the change of shape of the individual chloroplast, a phenomenon generally neglected by botanical teachers, though easily visible in such familiar laboratory types

as *Funaria* and *Vaucheria*. Dr. Senn describes the changes of shape in a number of types, and discusses the parts played in causing them by light, temperature, and chemical and other agencies. His general conclusion is that change of shape of the chromatophore is occasioned by "diffuse," not directive stimuli.

The main mass of the book deals, however, with changes in position of the chromatophores in the cell. Eight different patterns of distribution are recognised—epistrophe, apostrophe, systrophe (round the nucleus), peristrophe (uniformly round the cell-walls), antistrophe (on the wall facing the light), diastrophe (on the wall facing the light and on that opposed to it), parastrophe (in shaded parts of the cell), and escharostrophe (at the focus of the rays of light entering the cell). The conclusion is drawn that change of position of the chromatophores in the cell is the result of "tropic tactic [taxis] stimulus," in which the direction of the stimulus (for instance, light) does not as such determine the result, but only does so indirectly by involving a difference in intensity. According to Dr. Senn the distribution of the chromatophores in the cell is not the result of a simple stimulus emanating from the general protoplasm or released by differences in turgidity, but is the consequence of several types of irritability (phototaxis, chemotaxis, thermotaxis, osmotaxis) possessed by the chromatophores, which thus react in the same manner as free zoospores or Protozoa.

An appendix treats of the refractive index of the plant cell.

In a brief notice it is impossible to do justice to the wealth of detail in the book, which, except in the case of the special investigator, is one to be consulted rather than read through; indeed, the present reviewer confesses that he has not read the whole of the 376 pages of text.

Apart from containing the results of prolonged research and numerous observations, this critical book derives value from the thorough manner in which the author considers and does justice to the work of his predecessors, also from the repeated summaries of the conclusions arrived at concerning the various problems investigated, and from the rich bibliography and excellent index. The book, in fact, is one that should at least be in the library of every botanical institute.

MODERN ALGEBRA.

- (1) *A New Algebra.* By S. Barnard and J. M. Child. Parts i.-iv., with answers. Pp. x+534. Price 4s. Part iv., with answers. Pp. x+(301-466). Price 1s. 9d. (London: Macmillan and Co., Ltd., 1909.)
- (2) *College Algebra.* By Dr. S. C. Davisson. Pp. ix+191. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1909.) Price 7s. 6d.

(1) FEW branches of elementary mathematics have escaped the hand of the reformer during the last ten years. That this is a healthy symptom is unquestionable, for at least it points to a revival of interest, which cannot but infuse fresh life into a subject that the monotony of time may render arid and perfunctory. What measure of favour is to be

accorded to each set of changes must necessarily depend on the view that is taken of the purpose of a mathematical training in our educational system. It is not easy to form a combination of what is useful with what is interesting; and still less is it a simple matter to determine how far it is judicious to discuss at an early stage the fundamental ideas which underlie each branch of mathematics. But at the present time we believe that there is a dangerous tendency to pass over all considerations of mathematical philosophy as too difficult or uninteresting. We therefore welcome the present volume, which is a real attempt to build up an elementary course of algebra on the fundamental concepts of number and the operations to which it is subject.

The book is divided into four parts; the first deals with positive numbers, the second with zero and negative numbers, the third with irrationals, and the last with the more advanced applications, such as simultaneous quadratics, proportion, progressions, and the variation of simple functions. Each new idea that occurs is explained at considerable length in the text with admirable clearness, and is usually illustrated by graphical examples. In practice, no doubt, this will be used as the substance of an oral treatment, for few pupils will be sufficiently mature to be able to read and assimilate it unaided. There are abundant examples, a useful number of test papers, and an index which should prove of great practical value. We hope that this book will be widely used, for its principles are sound, and it introduces the student to a number of ideas that are both stimulating and instructive.

(2) This volume is intended to be used for a revision course. Stress is therefore laid on such features of the subject as are apt to be dealt with rather cursorily, or even omitted during the first reading. At the same time, however, the plan of the book is not designed to meet the wants of the professional mathematician, but to suit those who need a reasonably complete knowledge of the elementary principles of algebra. The remainder theorem and the principle of undetermined coefficients are placed in an early chapter; the section on linear equations contains also the fundamental properties relating to the roots of equations of any degree; and the theory of simultaneous equations is expanded to include an elementary account of the use of determinants. By such means as these, the author has provided a course which is admirably adapted for a second reading. The treatment is fresh and vigorous, the explanations are clearly put, and great care has been taken to ensure that the student really understands the nature of the various operations which he is called upon to perform.

OUR BOOK SHELF.

Les Tremblements de Terre. By l'Abbé Moreux. Pp. vii+378. (Paris: Henri Jouve, 1909.) Price 4 francs.

On June 11, 1909, towns in south-eastern France, and particularly those in the district of Provence, were shattered by an earthquake. The places which suffered most were Salon, Lambesc, Saint-Cannat,

Rognes, and Le Puy-Sainte-Réparate. Roughly speaking, the damage done to structures was estimated at 16,000,000 francs, which means something more than half a million sterling. From a monetary point of view this is a large sum, and it no doubt represents the effects of an unusually large earthquake. Had a similar rock adjustment taken place beneath a large city this sum would have been greatly magnified. The damage at San Francisco has been estimated at 70,000,000 sterling. Naturally, the disaster excited the imagination, and survivors have speculated on the cause of earthquakes. One outcome of the thoughts which were so rudely created is the book by the Abbé Moreux.

The author has read much about earthquakes. At the outset, although he tells us that his writings are not addressed to specialists, he has taken pains to popularise speculations about which specialists have but slight knowledge. He gives us a series of pictures of the ruins, tells us about the heartrending cries of the people, the arrival of the doctors, the erection of huts, and the generosity of the Pope. Next we read about possible premonitory signs. We are told that before the earthquake people suffered from vertigo, clocks struck wrongly, whilst pigeons flew about rather than going to rest. One interesting picture, which is not unlike the Cullinan diamond, is that of our pyramidal earth, the fourth corner of which was found by Sir Ernest Shackleton.

Reference is made to recent investigations relating to seismology, from which we learn that our world has a rigidity double that of steel. Volcanic and seismic effects are not directly connected, but earthquakes are in part the result of tectonic adjustments. They hold a relationship to the wobbling of the pole, fluctuations in barometric pressure, the change of seasons, lunar and solar attractions, and to internal convection currents. Earthquakes explain certain perturbations of magnetic needles and earth currents, whilst they are closely associated with solar radiation. The periodicity of earthquakes and their prediction are subjects which are not overlooked, whilst many pages are devoted to construction in earthquake countries, and to the mitigation of disasters. The relationship of pressure to temperature as we descend in the earth, and the fact that bodies may during crystallisation, or when they pass from the fluid to the solid state, suddenly expand, are phenomena which the Abbé discusses at considerable length. In fact, we are told that the shock accompanying such expansions may be the principal cause of many earthquakes.

It is an interesting little book, and will furnish many with subjects for speculation which have never crossed their minds before.

J. MILNE.

The Methods of Textile Chemistry, being the Syllabus of a Lecture Course adapted for use in Textile Laboratories. By Dr. F. Dannerth. Pp. viii+164. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1908.) Price 8s. 6d. net.

If the author had employed the title "Some Methods of Textile Chemistry" in place of the one he has chosen he would have erred on the right side. But to attempt to deal with the whole subject of textile chemistry—one of the most difficult and involved branches of analytical chemistry—in 120 small octavo pages of large type can scarcely result in anything of real value, even if the work is done as well as it is possible to do it. But when, as in the present case, the information is badly arranged, containing much that is superfluous if not useless, while omitting many matters of fundamental importance, and is not without a liberal sprinkling of mistakes and inaccuracies, the

inevitable result is a dismal failure. It is not quite clear for what class of reader the work is really intended, for in the preface we read that it "is intended to be a source of information and ready reference for the textile chemist," while on the title-page it would appear from the continuation of the main title, "being the syllabus of a lecture course adapted for use in textile laboratories," that it might be intended for some other purpose, possibly for teaching. In either case it has missed its mark.

These "knowledge in a nutshell" publications on technical chemistry, of which there appears to have been an increasing supply of late years, may be just the sort of thing that please people who like that sort of thing, but although there are a few exceptions, it is doubtful whether they do much good, while, on the other hand, they may do distinct harm through creating, under pretentious titles, a totally misleading impression of the subject as it presents itself in actual practice.

Naturwissenschaftliches Unterrichtswerk für höhere Mädchenschulen. By Prof. Dr. K. Smalian. Auf Grund der Bestimmungen vom 19 December, 1908, über die Neuordnung der höheren Mädchenschulwesens in Preussen bearbeitet von K. Bernau. II Teil: Lehrstoff der VI Klasse. Pp. 80. Preis 1.80 marks. III Teil: Lehrstoff der V Klasse. Pp. 127. Preis 2.25 marks. (Leipzig: G. Freytag; Vienna: E. Tempsky, 1909-10.)

IN the early part of last year a notice appeared in NATURE of Dr. Smalian's "Leitfaden der Tierkunde für höhere Lehranstalten," a work comprising a zoological text-book in separate fasciculi intended for the use of the various classes in German high schools. The fasciculi now before us form part of another work designed on somewhat similar lines for the use of girls' schools, but including botany as well as zoology. The general commendation bestowed on the "Leitfaden" may be extended to the present text-book, with the addition that we have little fault to find with the coloured plates of animals, while those of plants are excellent examples of German colour-printing, and worthy of all praise. Each of the two fasciculi now before us is divided into a botanical and a zoological portion; and it may be presumed that the same holds good for the other portion of the series. The zoological section of the second fasciculus is devoted to vertebrates, and that of the third to arthropods. A number of well-known species of mammals are, however, described in the first fasciculus.

The general plan of the work is similar to that of the "Leitfaden," the various orders being treated in systematic order, and a certain number of typical species being selected for comparatively full notice, while other groups are treated more briefly. In the case of the species selected as types, leading features in the external form and structure and noticeable traits in the matter of habits are touched upon; and throughout the work technicalities are, so far as possible, avoided. The only scientific names introduced are those of species, ordinal and family groups being referred to by vernacular designations. In the main the species represented in the illustrations seem to be correctly named; but in one of the coloured plates the monkey designated *Cercopithecus sabaues* is clearly *C. aethiops* or one of the allied forms, as it has the distinct white brow-band of the latter, which is absent in the former. So far as we can see, the book appears admirably suited for its purpose, although it by no means follows that it would be equally well adapted to the needs of English schools.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. No notice is taken of anonymous communications.]

The Meaning of "Ionisation"

IN asking for precision of language (p. 487), Prof. Armstrong shows how much he has fallen behind his time. If he had kept abreast of the recent developments of the principles of science, he would know that to be precise means running the risk of being wrong, which is to be avoided at all costs. Prof. Armstrong evidently belongs to an antiquated school which believed that scientific discoveries are made by forming definite ideas of things, even though these cannot be seen and handled. That is a standpoint which is abandoned, and we have entered on a new era. Science now aims purely at obtaining an equation which, without committing itself to any definite views, gives the required relationship between the brain impressions taking place in that particular dimension of a many-dimensional complex, which we identify with time. I am sorry if in this statement I have committed myself to the existence of a brain—it was lapse due to a weak concession to the prejudices of my youth, and would have been impossible in a thorough-going adherer to the new faith.

But to come to the point. If Prof. Armstrong will bring the theory of entropy to bear on the principle of least resistance to a cheap appearance of sagacity, he will discover, not what Arrhenius meant by ionisation—that is unimportant—but what he ought to have meant and would have meant if he were a chemical physicist such as we make them now. A. S.

The Fertilising Influence of Sunlight.

THE letter on the above subject by Mr. and Mrs. Howard in NATURE for February 17 raises a question of much scientific interest and of considerable importance in tropical agriculture. In some of the text-books it is stated that the hot sunshine of tropical or subtropical climates must injure the productiveness of the soil, since it kills bacteria. On the other hand, experiments on the partial sterilisation of soil by other means—such as heat or volatile antiseptics—shows that the killing of bacteria (as distinct from spores) leads to an increased, and not a diminished, productiveness. The apparent discrepancy is now cleared away, and we have Mr. and Mrs. Howard's authoritative statement that strong sunlight has beyond question a beneficial effect on productiveness.

There is a close resemblance between the effects they describe and those that have been obtained with partially sterilised soils by myself in conjunction with Dr. Darbishire and with Dr. Hutchinson; in all cases the effect is that of a dressing of nitrogenous manure. Dr. Hutchinson and I have traced this to an increased rate of decomposition of organic matter after partial sterilisation, and have shown that the increased activity is due to the destruction of some agent, probably large organisms, which had previously interfered with bacterial development. The question is, Could sunlight partially sterilise a soil and kill the large destructive and competing organisms that we suppose limit productiveness?

There are at least three factors involved: sunshine dries the soil, heats it to a certain temperature, and may have a direct chemical action fatal to the cell. We are at present studying the effect of dryness and of temperatures lower than 100° (at which we have previously worked), but the direct effect of sunshine is not easily investigated here. Some preliminary experiments I made at Wye during the summer of 1906 indicated that soil exposed to bright sunshine for a period of ten days subsequently absorbed oxygen more rapidly, i.e. showed a higher rate of bacterial activity, than another lot kept shielded from the light. The effect was comparable with that produced by volatile antiseptics, and, so far as the experiment goes, it shows that sunlight could, equally with these, remove the factor limiting productiveness in ordinary soils. I have several times attempted to extend the experiment, but

have been unfortunate in timing it, and have missed the continuous spells of strong sunshine.

We could not hope to attack the problem so successfully here as in India, and it would be interesting to have some Indian work on the subject. The experiments of Mr. and Mrs. Howard in conjunction with Mr. Leake on the "fertilising influence of sunlight" may be expected to throw a great deal of light on a very important problem.

Rothamsted Experiment Station, Harpenden.

The Spectrum of Bacterial Luminosity.

In the course of some experiments on the phosphorescence of minerals, especially with regard to the emission of ultra-violet radiation, it was suggested to me by Prof. Strutt that it would be of interest to examine the spectrum of the light from luminous bacteria. Through the kindness of Sir James Dewar, Prof. Strutt was enabled to furnish me with a dish containing bacteria produced from fish which, when viewed in a darkened room, were seen to glow with a greenish-blue light bright enough to enable one to read a watch. The dish was placed in front of the slit of a quartz spectrograph of rather crude design, constructed with lenses of short focal length so as to utilise the light available to the fullest extent. A special rapid photographic plate was first exposed to the radiation from the bacteria for forty-six hours, and then to the light from a cadmium spark for one second.

The plate when developed exhibited strong evidence that the spectrum of the light emitted by the bacteria consisted of a continuous spectrum extending from wave-length 5000 (the lower limit of the sensitiveness of the plate) to wave-length 3500 tenth-metres, together with a well-marked bright band of wave-length 4000 approximately. Practically the same result has been obtained from bacteria produced from meat. The greater portion of the radiation is absorbed by a film of nitroso-dimethylaniline.

Mr. J. E. Barnard, in his article on luminous bacteria (*NATURE*, April 10, 1902), states that the light emitted by these organisms is confined to a small portion of the visible spectrum, and never extends into the ultra-violet or infrared. The photographs I have obtained indicate that in some cases these bacteria emit ultra-violet radiation, and I hope with another spectroscope, now in course of construction, to obtain more definite information.

Self-fertilisation and Loss of Vigour.

SOME of your readers will remember that in the introduction to "Cross and Self-fertilisation of Plants," Darwin inserts a report by Sir Francis Galton on seven tables of measurements relating to the relative heights of the offspring of cross and self-fertilised plants. "It is a very remarkable coincidence," says Galton, "that in the seven kinds of plants the ratio between the heights of the crossed and the self-fertilised ranges in five cases within very narrow limits. In *lea mays* it is 100 to 84, and in the others it ranges between 100 to 76 and 100 to 86."

If Table A of Darwin's book be referred to, it will be found that these ratios recur in many more than five cases. I write to suggest—with great diffidence, as I am a mere amateur in such matters—that the persistence of these ratios is capable of simple explanation on the basis of the Mendelian theory of heredity.

The distribution or "array" of a Mendelian family, crossed at random, is given by the expansion of $(3D+R)^n$, where n = the number of pairs of characters involved, and the powers of D and R respectively represent the number of dominant and recessive somatic characters of each individual. If, now, each individual be self-fertilised, the array can be shown by simple algebra to become $(5D+3R)^n$. Similarly, in the next self-fertilised generation, the array becomes $(9D+7R)^n$, and so on. The average number of dominant characters in each generation is, consequently, $\frac{2}{3}n$; $\frac{4}{3}n$; $\frac{5}{3}n$, &c., which give the ratios 100 : 83 : 75, &c.

It is surely something more than a "remarkable coincidence" that these ratios agree in so many cases with the ratios observed by Darwin?

Vision and Colour Vision.

WITH reference to the comment on my lecture at the Royal Society of Arts in *NATURE* of February 17, I did not give the evidence in favour of the visual purple being the visual stimulus transformer on account of the time at my disposal. This evidence is very strong, and the facts are inexplicable on any other hypothesis. Many physiologists have tried to assign different functions to the rods and cones, but these theories have failed because all the functions which were said to be the exclusive property of the rods have been found, only gradually diminished, in the fovea, in which only cones are present. For instance, von Tschermak, Hering, Hess, Garten, and others, have found the Purkinje phenomenon, the variation in optical white equations by a state of light and dark adaptation, the colorless interval for spectral lights of increasing intensity, the varying phases of the after-image, in the fovea, only gradually diminished. The complete absence of any qualitative change between the foveal and extra-foveal regions is a very important fact in support of the hypothesis that the visual purple is the visual substance. There is also the fact, mentioned by Helmholtz, that a perceptible interval elapses before we see with the fovea, after the rest of the retina, when the eye has been previously some time in darkness. Hess has also pointed out that the recurrent image is present, but retarded at the yellow spot. All these observations and many others agree with my statement that the visual purple can be seen between but not in the cones of the fovea.

The Methods of Bird Fanciers.

MAY I ask for information on the following matter?

Happening to be walking in a poor quarter of Acton (Chiswick) with a friend, we were astonished to see hanging outside a house, on either side of the door, two small bird-cages completely enveloped with dark cloths carefully fastened. The cages evidently contained birds, for from one of them came the song of a chaffinch.

Had the birds suffered the torture of having their eyes put out to make them sing, or is this a method resorted to instead of blinding them?

The caging of wild birds is so very cruel that it should be exposed in all its barbarous ways.

Some of the wild birds are kept in such small cages that there is scarcely room for them to turn round.

E. L.

It is customary for bird fanciers amongst the lower classes to match one chaffinch against another, often in public-houses, the bird which sings the largest number of notes being adjudged the victor. When the cages are carried about they are usually wrapped up in dark cloths, and it is said that one of the objects of keeping the birds in the dark is that they should imagine it is night while they are covered, and that on the cloth being removed, thinking it is day, they burst forth into song. As it is believed by some that birds sing better when they are blinded, it may be, as "E. L." suggests, that the covers were used in the case mentioned either to avoid practising the cruelty of putting out the birds' eyes or so that the fancier might not render himself liable to the punishment for doing so. More likely the birds that were kept covered were newly caught, and the object was to prevent them from dashing themselves against the bars of the cages in their endeavours to escape. As has often been pointed out, one reason for the smallness of the cages used is to lessen the danger of the birds killing themselves, as in a larger space they could begin to fly and would strike with greater force.

WILFRED MARK WEBB.

Title of the Natural History Museum.

IN *NATURE* of February 24 (p. 489) Mr. Hobson suggests as both "suitable and adequate" that it should be called the "British Museum of Natural History."

Why not omit "British" and "of," re-arrange the order of the words, and call it "The Natural History Museum," adding "London" if necessary?

Torquay.

F. HOWARD COLLINS.

NORTH POLAR OCEANOGRAPHY.¹

A HANDSOME volume full of useful information has been given to oceanographical science by H.R.H. the Duke of Orleans, the result of a cruise in the Greenland Sea during the year 1905. This is one of a series of Arctic cruises His Highness has been making for a number of years, the last having been during the summer of 1909. On each of these voyages the Duke of Orleans has carried with him an excellent scientific staff on board his yacht, the *Belgica*, a vessel already known in Antarctic exploration. Among those who have been with him are Dr. Récamiér, who has accompanied the Duke on each of his previous voyages, as well as Captain Adrien de Gerlache, formerly leader of the Belgian Antarctic expedition, M. E. Mérite, the artist-naturalist, and Mr. E. Koefoed.

to west over to the Greenland coast in as high a latitude as $75^{\circ} 30' N.$, a region which has been inaccessible to other expeditions trying it. Along this route a complete set of soundings and serial temperature and salinity observations were made. The coast of Greenland was met on July 27, and the Duke landed on an island, rich with Arctic vegetation, just south of Cape Bismarck, and which he named "Ile Marousia." At 8 a.m. on July 28 the *Belgica* was four miles north of Koldewey and Payer's cairn, the furthest north point of the German expedition of 1870. At noon the *Belgica's* position was $77^{\circ} 20' N.$, $18^{\circ} 20' E.$, and in the evening a party landed on a previously unknown island, which was named Ile de France, the south-east cape of which, in $78^{\circ} 38' N.$, $17^{\circ} 36' W.$, was named Cape Philippe. Here the French colours were hoisted. Koefoed found nineteen phanerogams, seven mosses, four fungi, and six lichens; hares,

FIG. 1.—The *Belgica* in land ice on August 4, 1905 (Lat. $77^{\circ} 29' N.$, Long. $18^{\circ} 31' W.$).

The volume opens with a narrative of the voyage and an extract of the ship's journal, by Captain de Gerlache. The *Belgica* left Tromsø on June 3, and, passing northward to the west of Spitsbergen, sighted Prince Charles Foreland in exceptionally clear weather, reaching $80^{\circ} 20' N.$ in this longitude. From this point the Duke attempted to push westward towards Greenland, not to establish "un vain record," but to carry on serious scientific investigations in an unexplored region of the Arctic Ocean. This attempt was repulsed by heavy ice, which drives southward from the polar basin between Spitsbergen and Greenland. The special object was to verify the hypothesis that a ridge separated the Greenland Sea from the North Polar basin, but though unsuccessful in this attempt, the expedition succeeded in crossing from east

plarmigan, foxes, and lemmings abounded. The remains of Eskimo encampments were also found.

At midnight on July 30 the *Belgica* was in $78^{\circ} 16' N.$, $16^{\circ} 48' W.$, or 167 miles further north than the *Germania* in 1869. From this point the *Belgica* pushed eastward, and thirty miles eastward, after getting shallowing soundings of 245, 120, and 55 fathoms, struck bottom at 32 fathoms, and named this bank the Belgica Bank. Six miles to the south-east of this point the water deepened again to 109 fathoms. de Gerlache suggests that there may be an island in the vicinity, noting that two crows and a walrus were seen. After this the Duke returned by more or less the same route so far as Cape Bismarck, and from there in a more or less southerly direction in, and along, the edge of the Greenland pack, which they lost sight of on August 21 in about $67^{\circ} 30' N.$, $24^{\circ} E.$ It is satisfactory to note that at almost the furthest north point reached a well determined position

¹ Duc d'Orléans. "Croisière Oceanographique accomplie a bord de la *Belgica* dans la Mer du Grönland, 1905." Pp. v+568; lxxix plates. (Brussels: Bulens, 1907.) Price 100 francs.

was obtained, viz. $78^{\circ} 13' N.$, $16^{\circ} 30' W.$, and that the coast was mapped approximately to $79^{\circ} N.$ All that is mapped is satisfactorily determined except Cape Bourbon and Cape Bergendal; the distances of which were judged, only single angles being taken. A good declination was obtained in $77^{\circ} 35' N.$, the result being $37^{\circ} N.W.$

Full extracts of the journal compiled on board are published. Here we are given the time and position, the weather, the sea, ice observations, stations, and movements of the

south. Plate lx. shows deposits from the north of Scotland to north of $80^{\circ} N.$ All is blue mud, except the globigerina ooze, which pushes north-east from west of Scotland to within 240 miles of Bear Island, broken only by the volcanic muds of Iceland and the Færøes.

Dr. C. H. Ostenfeld treats the botany in a systematic manner, but beyond the further northern extension of known East Greenland species there is naturally nothing very novel.

Mr. Einar Koefoed and Captain de Gerlache give

FIG. 2.—Cape Philippe.

ship, and the animals met with, in a thoroughly systematic manner. Next come a list of eighty soundings and fifty oceanographical stations, showing good solid work. The soundings vary from 12 to 1846 fathoms. Many hydrographic observations were taken, and plankton and other fishing was carried on.

Meteorology has been well handled by Dr. Dan la Cour, the observations of twenty-two ships having been considered, as well as thirty-eight land stations, though one misses the observations taken by Scottish whalers in the Greenland Sea and Davis Straits.

an account of oceanographical equipment which, with the exception of the excellent Lucas sounding machine, was mostly Danish or Norwegian. There follows a useful journal of the fifty stations, mostly in the Greenland and Spitsbergen seas. This journal gives a summary of the hydrographic and other work done at each station, and lists of planktonic species. Messrs. B. Helland-Hansen and E. Koefoed then proceed to discuss the hydrography of the expedition, and no expense is spared in enhancing this part of the report with a very excellent series of useful, interesting, and

FIG. 3.—Duke of Orleans Land, near Cape Amelia

There are ninety-six synoptic charts for July and August, 1905, which are of great interest.

Mr. O. B. Boggild reports on the geology. He has a theory of a submarine moraine existing to the east of Greenland, running parallel with the coast, but this is scarcely supported by the bathymetrical chart (plate lvi.). The geological observations at Cape Saint Jacques ($77^{\circ} 36' N.$), on the Ile de France, are of most interest. Here there are gneisses and schists, and possibly some Devonian rocks probably identical with those that Nathorst found further

beautiful plates and maps for the purpose of demonstrating the distribution of depths, temperature, salinity, currents, &c. Most of the introduction is a summary of the hydrographic work of previous expeditions to the Greenland seas, but Messrs. Koefoed and Helland-Hansen have made no mention of Mr. Leigh Smith's work of 1870, nor of that done on board the *Princesse Alice* during 1898 and 1899, mostly by Mr. J. Y. Buchanan and the reviewer. Leigh Smith was the first to notice the intermediate warm layer in these seas which is specially dealt with by

Messrs. Koefoed and Helland-Hansen, yet no mention of this veteran's name or work is made. Buchanan, Nansen, Bruce, and others have also observed this phenomenon. We doubt also if some of these old observations are less exact than those of more recent date. The Buchanan methods give, for instance, observations of great exactitude, and certainly equal to any of the most recent observations of the younger Scandinavian school of oceanographers.

Part ii. deals with instruments and methods; and here useful discussion could be entered upon, as, for instance, on the question as to whether one is able to obtain results of greater accuracy with the more finely graduated Richter thermometer on the deck of a ship in the polar regions, with discomforts of mist, sleet, snow, wind, and weather. A stronger marking and coarser scale certainly in many cases will give more accurate results than the very finely-graduated scale of the Richter thermometer instruments, as the reviewer knows by extensive work on board ship in all weathers and almost all latitudes. The question of a ridge rising to within about 400 fathoms of the surface is discussed, but so far no absolute proof of this has been obtained, owing to the great difficulty of penetrating the polar pack—some of the heaviest ice in the world—between the north of Spitsbergen and the east of Greenland. The Duke of Orleans has, however, come nearer accomplishing this important investigation than anyone else, for he obtained a more complete line of soundings two degrees further north in the middle longitudes of the Greenland Sea than any previous navigator.

The authors divide the Greenland Sea into three areas:—

- (1) East—having high temperatures and salinities, being influenced by the Gulf Stream.
- (2) Middle—a deeper region with mixed conditions.
- (3) West—a shallower region with low temperatures and salinities, being influenced by the polar current.

Plate lxii. gives a chart indicating the stations of the *Belgica* and those of other expeditions in the Greenland seas and regions adjacent; but again we miss the stations of Leigh Smith, 1870, those of Bruce (S.Y. *Blencathra* of Major Andrew Coats), 1898, and those of the Prince of Monaco, 1898-9. Many interesting problems are raised by the temperature, salinity, and current observations made by the Duke of Orleans and his staff, and not least of them is the theory of the Spitsbergen-Greenland ridge already referred to, but it is impossible in this short review to enter fully into all these questions.

The zoology of the voyage, discussed by Prof. C. Hartlaub, Messrs. D. Damas, E. Koefoed, and M. J. G. Grieg, occupies more than a third of the volume. The plankton work is very exhaustively and thoroughly handled by Messrs. Damas and Koefoed. Several dredgings in depths down to 750 fathoms also secured a number of interesting benthic forms. The numerous inset maps and sectional diagrams and tables are especially useful, bearing as they do on the distribution of plankton.

The plates by Werner and Winter maintain the high reputation this firm has justly won. M. Édouard Mérieux's work is reflected throughout the natural history of the expedition, though much of this excellent artist's colour work only appears in the Duke of Orleans's less technical work, "A Travers la Banquise du Spitzberg au Cap Philippe." Dr. Récamier, too, did much to make the voyage a success. There are useful sketches of the new coast between 77° and 79° N., and some most excellent half-tone blocks, many of which show polar ice well; the frontispiece is especially to be commended as "a thing of beauty." One regrets to see that glazed paper is used

instead of pure rag paper, which actually produces richer effects and is infinitely more durable.

Altogether the Duke of Orleans is to be most heartily congratulated, not only for having personally conducted all the above work, but even more so for having placed the observations and material gathered during the voyage into competent hands for examination and description, and for having spared no trouble or expense in bringing out a volume which is second to none as a monumental contribution to the oceanography of the Arctic Ocean. Too often polar expeditions are dispatched by the help of men of means, but these same people have little or no conception of making use to the full extent of the material, obtained with great care, toil, and trouble, on the return of the expedition. The excellent work of many trained men of science who accompany such expeditions is in consequence largely wasted. The Duke of Orleans, however, has realised the full value of this subsequent work, and the thanks of the scientific world is due to him for having seen it through so handsomely to the finish.

WILLIAM S. BRUCE.

AÉROPLANE STABILITY.

IN 1896 I had the pleasure of attending a lecture on naval architecture given before the British Association in Liverpool by the late Dr. Francis Elgar, F.R.S. I had learnt the theory of the metacentre in my undergraduate days, but it came to me as a great surprise to learn that this theory had only been evolved after many ships had foundered, owing to want of theoretical knowledge of their conditions of stability.

I was interested in aerial navigation at the time, and although I had not got further than throwing gliders, it was evident from their behaviour that a mathematical theory of stability must necessarily be of even greater importance in connection with aerial navigation than with naval architecture, and I wrote in *Science Progress* to the effect that if the future development of artificial flight were not to be a repetition of the chapter of accidents by which naval architects had gained their theoretical knowledge, there would be abundant work for mathematicians in reducing the conditions of stability to pure calculation.

About the year 1903 I noticed that if a glider or other body is moving in a resisting medium, such as air, in a vertical plane with respect to which it is symmetrical, the small oscillations about steady motion in that plane are determined by a biquadratic equation; and Prof. Love directed my attention to the condition of stability given by Routh. Mr. W. E. Williams was a post-graduate student in my department, and with his collaboration we published a paper on "The Longitudinal Stability of Aerial Gliders" (Proc. Royal Soc., lxxiii.), which was intended to direct attention to the general method, and the importance of further investigation, rather than to furnish a complete solution of the problem.

Mr. Williams shortly afterwards obtained a so-called "Research Fellowship"; but "research" in this case was interpreted as meaning practical work done in a physical laboratory away from Bangor, so the award had the effect of preventing the continuation of original work on this important problem. On the other hand, the necessity of providing, with one assistant, classes in all grades of pure and applied mathematics, and of devoting special attention to the requirements of junior students whose knowledge of the "first four books" and of arithmetic had been neglected at school, left no time for me to carry on the work single-handed. It is only since the comparatively recent abolition of these *infra* university-

courses that I have been able to give any attention to the subject.

Some criticisms having been raised by the late Captain Ferber, mainly referring to the form in which the conditions of stability were stated, I suggested his developing the work as I had not time to do so. His results were published in the *Revue d'Artillerie*, October and November, 1905, and include a discussion of lateral as well as of longitudinal stability.

At the beginning of last year the work of my department was, for some unknown reason, exceptionally light, and I had in Mr. E. H. Harper an assistant well able and willing to collaborate in a much more exhaustive investigation both of longitudinal and lateral stability. About October I received a formal letter of inquiry from the Government Committee, in an envelope which I at first took for an income-tax application, and in reply stated that what I wanted was a small grant to enable me to devote my whole time to this work. I received a reply that the committee "regretted," &c., but that "very great interest was taken" in the work. The main difficulties of the subject have, however, now been practically cleared up, though a long time must elapse before a detailed written account is ready for publication. Had any prizes been offered in England for which such an investigation would be eligible, the delay might have been avoided or shortened.

Reference must be made also to Mr. Lanchester's remarkable investigations, published in his "Aërodynamics," and to the appearance of a German translation of the preceding volume, "Aërodynamics," shortly after its publication in English.

It is here proposed to give a general idea of the peculiarities of aeroplane stability as deduced from my work, and a comparison with Ferber's and Lanchester's methods; though with regard to the latter is rather difficult for any critic to be sure of not misjudging the author's intended meaning.

It is necessary that the distinction between equilibrium and stability should be kept in mind. An aeroplane is in *equilibrium* when travelling at a uniform rate in a straight line, or, again, when being steered round a horizontal arc of a circle. A badly balanced aeroplane would not be able to travel in a straight line. The mathematics of aeroplane equilibrium is probably very imperfectly understood by many persons interested in aviation, but it is comparatively simple, while the theory of stability is of necessity much more difficult.

It is necessary for stability that if the aeroplane is not in equilibrium and moving uniformly it shall tend towards a condition of equilibrium. At the same time, it may commence to *oscillate*, describing an undulating path, and if the oscillations increase in amplitude the motion will be unstable. It is necessary for stability that an oscillatory motion shall have a positive modulus of decay or coefficient of subsidence, and the calculation of this is an important feature of the investigation. A slight reference to this question of rolling is given by Chatley on p. 99 of "The Problem of Flight," but he seems to have overlooked the fact that this damping may be, and often is, negative in the case of unstable aeroplanes.

At the present time it is certain that aviators rely on their own exertions for controlling machines that are unstable, or at least deficient in stability, and they even allege that, owing to the danger of sudden gusts of wind, automatic stability is of little importance. Moreover, even in the early experiments of Pilcher, it was found that a glider with too V-shaped wings, or with the centre of gravity too low down, is apt to pitch dangerously in the same way that increasing the metacentric height of a ship while

increasing its "statical" stability causes it to pitch dangerously. It thus becomes important to consider what is the effect of a sudden change of wind velocity on an aeroplane. If the aeroplane was previously in equilibrium it will cease to be so, but will tend to assume a motion which will bring it into the new state of equilibrium consistent with the altered circumstances, *provided that this new motion is stable*. Thus an aeroplane of which every steady motion is stable within given limitations will constantly tend to right itself if those limitations are not exceeded. Excessive pitching or rolling results from a short period of oscillation combined with a modulus of decay which is either negative (giving instability) or of insufficient magnitude to produce the necessary damping.

The new work depends very largely on the property that for a system of *narrow aeroplanes inclined at small angles to the line of flight* approximate methods may be used, greatly simplifying the algebra, and enabling the various oscillations to be separated and their moduli of decay to be calculated approximately. Of the six equations of motion as applied to the small oscillations of a symmetrical aeroplane, three determine oscillations in the plane of symmetry, and lead to conditions of *symmetric* or *longitudinal* stability. The other three determine asymmetric or skew symmetric oscillations, leading to conditions of *asymmetric* stability. The three equations in each set are mutually interdependent, but independent of the other three, thus accounting for the fact that Lanchester found it impossible to separate "lateral" and "directional" stability. Failing any better terminology, I have provisionally adopted the term "asymmetric" stability.

Of the two, symmetric stability presents by far the simpler problem. For the systems above mentioned there are two symmetric oscillations, one of long and one of short period. The short-period oscillation consists mainly of an oscillatory motion of the centre of gravity perpendicular to the line of flight (*i.e.* a vertical oscillation if the aeroplane is moving horizontally), combined with a rotatory oscillation about the centre of gravity. To a first approximation it produces no fluctuations in the velocity in the line of flight, and is unaffected by head resistance or fluctuations in the propeller thrust, provided the latter passes through the centre of gravity of the aeroplane, as has been assumed in many of our calculations. The condition of stability depends only on the areas and positions of the aeroplanes relative to the centre of gravity, and is independent of the inclinations or angles of attack of the planes, the oscillations remaining finite when the planes are parallel. This condition of stability is generally satisfied in any arrangement which satisfies the other conditions of stability. It must not be overlooked, though it is very unlikely to give trouble. The corresponding *trajectory* or *curve of oscillation* is independent of the velocity, the actual *time rates* of oscillation and decay being proportional to the velocity.

In the slow oscillations the variations of velocity in the line of flight are a predominating feature. The trajectory is wave-like, the crests of the waves being more pointed than the troughs, and the descending parts steeper than the ascending ones. This is evidently the type of oscillation studied by Mr. Lanchester. One condition of stability is that the front plane (or planes) must be inclined at a greater angle than the rear ones. The second condition depends on the type of machine.

The terms "monoplane" and "biplane," as usually defined, refer to the question of whether a machine has not or has superposed planes. According, how-

ever, to a property which I call the *principle of independence of height*, this distinction does not affect stability to any appreciable extent. The important point is whether the weight is sustained partly by the front and partly by the rear planes, as in certain Voisin machines, or is wholly supported by the front planes, the rear ones acting merely as a tail in the neutral position. For a monoplane with neutral tail the condition of stability takes the form given by Lanchester, when the necessary substitutions have been made by making use of the condition of equilibrium. The reason why Lanchester's method leads to a correct result is to be sought in considerations of the peculiar nature of the oscillations, and in especial in the relative smallness of their modulus of decay. For a machine of the Voisin type, with sustaining surfaces arranged tandem, the condition of stability is nearly as simple, and certain modifications are sufficient to cover the case when the propeller thrust does not pass through the centre of gravity provided that this thrust is constant.

A very convenient plan in such cases is to suppose the actual machine replaced by an *equivalent monoplane*, with neutral tail, although if the inclinations of the planes be varied for vertical steering the equivalent monoplane will be changed.

The most remarkable result, however—and Mr. Harper was the first to point this out to me—is the *important effect on stability of the direction of motion in the vertical plane*. Longitudinal stability falls off rapidly when the aeroplane begins to rise, even if other things are constant. A monoplane would, under theoretical conditions, become unstable when ascending at an angle to the horizon of less than twice the angle of attack (or inclination of the main plane to the line of flight).

The effect of head resistance is to increase the stability, and a further increase occurs if the thrust of the propeller, instead of being constant, decreases when the velocity increases. By the use of three planes instead of two, an additional increase of stability can be obtained. On the other hand, if the aeroplane be gliding downwards the longitudinal stability is greater than in horizontal flight.

I think the above conclusions indicate a source of danger which may possibly have led to mishaps when aeroplanes have risen too rapidly in the air.

Captain Ferber's investigations, on the other hand, refer mainly to the stability of a single aeroplane as dependent on fluctuations in the position of the centre of pressure consequent on variations of the angle of attack. He assumes Joessels's formula, introducing two arbitrary constants in place of the numerical coefficients. The difficulty I have several times pointed out is that, if a plane is turning over, its rotational motion may affect the position of the centre of pressure, as well as possibly the resultant thrust, and no experimental information is apparently available on this point. For this reason the use of narrow aeroplanes is to be recommended, stability being secured by a tail or by two planes placed one behind the other. Moreover, the theory of narrow aeroplanes gliding at small angles affords the simplest introduction to a general study of aeroplane stability, just as geometrical optics in which aberration is neglected affords an introduction to a general study of lens construction. It is to be remembered that both the symmetrical and asymmetrical oscillations are determined by equations of the fourth degree, each in the form of a determinant of the third order containing the dynamical constants and resistance coefficients, and when this determinant has been expanded, *four* conditions of stability have to be satisfied, one being that Routh's discriminant

$BCD - AD^2 - EB^2$ shall be positive. Fortunately, for purposes of approximation, $CD - EB$ may be substituted for the last in many of the systems occurring in aviation. It will thus be seen that stability is a very complicated problem, and that approximate methods are essential.

Asymmetric stability is far more difficult of investigation than symmetric. It is necessary to take account of the separate effects of straight or horizontal aeroplanes, vertical fins, and bent-up or V-shaped planes. The late Captain Ferber's solution is based on the substitution for the actual planes of their projections on three coordinate planes (p. 46 of his paper). Unfortunately, even assuming the sine law of resistance, this substitution does not seem to give even the correct first approximation which is all the author claims. In particular, if the aërodrome is rotated about any axis in its plane of symmetry, couples are set up on the main aeroplane which have an important effect on the stability, but are apparently not included in his scheme. The final result is a biquadratic with one root equal to zero, and Captain Ferber regards an aeroplane as stable when it describes a helix; whereas such an arrangement should really be regarded as lacking in stability. The couples in question are taken account of by Lanchester, who uses what he calls "aërodynamic and aërodromic radii" to represent their effects. For a narrow aeroplane gliding at a small angle, the effect depends on the moment of inertia of the area of the plane about the vertical plane of symmetry. A horizontal tail of negligible lateral dimensions does not affect the asymmetric stability.

To secure stability, recourse must be had to vertical fins, or to bent-up aeroplanes or aërofoils. The effect of vertical fins (neglecting "wash") depends on their areas, and the first and second moments of these about the axes, and in studying them it is necessary to have recourse to the "principle of parallel axes." The sections in "Lanchester" on "fin resolution" practically embody this principle, but are a little difficult to follow; they suggest the path taken by an explorer who had not a compass to guide him to the mathematically direct road in the form of the principle in question. His conditions of stability seem reasonable deductions from the hypotheses he makes, but the conclusions must not be regarded as final. Both the necessary and the sufficient conditions of stability are really far more complicated, and it is highly improbable that the problem could have been carried much further without the elaborate use of analysis which I have found necessary, and the assistance of an independent calculator, which Mr. Harper has kindly provided. The only way of proceeding was to calculate the coefficients in the biquadratic for particular arrangements of fins and planes, starting with the simpler ones, and passing to more complicated ones *when one has become thoroughly familiar with the different terms and their meanings*.

For an aeroplane with one vertical fin only, the conditions of asymmetric stability require that the centre of pressure of the fin should be slightly in front of the centre of gravity of the machine, while at the same time it should be at a height above the centre of gravity large compared with its distance in front. Two of the conditions of stability are difficult to reconcile with the conditions of equilibrium, the difficulty increasing as the velocity increases and the angle of attack diminishes; moreover, they are inconsistent unless a certain relation holds between the radii of gyration of the machine and of the main supporting surface. It is doubtful whether this condition would be consistent with practical requirements.

The failure of practical aviators to obtain automatic stability may be due in no small measure to the number of conditions that have to be satisfied. A vertical fin in front might satisfy one condition of stability, and introduce instability through another condition, while a similar fin at the back might satisfy the second condition and introduce instability through the first. In either case the impression produced would be that the device secured automatic stability, but that such stability was a hindrance rather than a help, the correct interpretation being that the conditions of stability had not been sufficiently investigated. By abolishing the fins the aviator would obtain a machine with *defective stability*, i.e. with one or more roots of the biquadratic vanishing, and would find it easier to maintain his balance by artificial control than in the previous unstable arrangement.

Of arrangements with two fins, the cases have been considered where both fins are at the level of the centre of gravity, where one is above, and where both are above. The conditions of stability assume various forms, but there is one arrangement which appears to possess an exceptionally wide range of stability, and I have made provisional application for a patent in this connection.

A machine such as the Voisin type, with two planes of considerable span at different angles of attack, is more stable than one with a single sustaining system, and the difference is equivalent to a variation in the arrangement of the fins which is easily calculated.

The asymmetric oscillations of an aërodrome do not separate into two kinds, of long and short period, like the symmetric ones. As a general rule the biquadratic has one root determined approximately by the first two terms representing a quick subsidence, one root determined by the last two representing a slow subsidence, and a pair of roots determined by the middle terms representing a damped oscillation.

The inclination of the flight-path to the horizon has a considerable influence on the asymmetric stability. In several instances we found that instability occurs when an aërodrome is descending at an angle to the horizon the tangent of which is double that of the angle of attack of the main planes. Other arrangements become unstable when rising at more than a certain angle; in the best arrangement referred to above the stability is practically independent of the inclination. As the symmetric and asymmetric oscillations of an aëroplane are independent, it is important that it should preserve its asymmetric stability even when it is not in longitudinal equilibrium. The dependence of stability on inclination affords a very simple and likely explanation of certain "vagaries" described on pp. 342, 343 of Lanchester's "Aërodonetics"; account would, however, have to be taken of accelerations of the centre of mass in an exact comparison of theory with observation.

Bent-up or V-shaped wings lead to much more difficult analysis, and it appears that their effect is not exactly equivalent to any combination of vertical fins except in certain cases. A pair of "stabilisers" or small planes, which may be fixed at the extremities of the main aëroplanes at an angle of, say 45° , is equivalent to a single raised vertical fin if the planes of the stabilisers are parallel to the line of flight.

Mr. Harper has worked out the asymmetric stability of the Antoinette type with a single pair of bent-up supporting surfaces. The conditions of stability are satisfiable by furnishing the machine with a tail of suitable length, or by raising the dihedral angle of the V-shaped wings above the centre of gravity.

I should like to direct attention to the importance of eliminating the personal element in experimental

tests of aëroplane stability, by the use of models. The possibility of long-distance flights by skilled aviators having been demonstrated, there is not so much point in repeating these verifications as in extending our knowledge in other directions, and finding how far the element of skill can be dispensed with by effecting improvements in aëroplane design.

The stability of dirigibles opens up another field of study, on which we hope to do something during the coming year.

Owing to the attention now given to aëroplane construction, it appeared desirable to give, in the present article, an advance account of investigations which may not be ready for publication *in extenso* for some time to come.

G. H. BRYAN.

Added January 27, 1910.—The *Aëronautical Journal* for January, now to hand, includes a short abstract, illustrated by badly executed diagrams, and containing numerous uncorrected printers' errors, in which the symmetric stability of a single-surfaced aërodrome without tail is made to depend on a cubic instead of a biquadratic equation. This result is obtained by the very doubtful method of "assuming V to be constant for a short period," that is, neglecting fluctuations in horizontal velocity. Owing to this assumption the conclusions reached may perhaps represent the conditions that the machine may be stable with reference to the shorter oscillations, but not with respect to the longer ones, and the inference that a machine can be much more stable at moderate velocities than is generally supposed must not be regarded as conclusive.

THE WORK OF THE WOBURN FRUIT FARM.¹

AMONG the profusion of agricultural and horticultural reports, many of which can at best be said only to possess a very ephemeral interest, it is pleasant to come across something of permanent and abiding value, work carefully executed and followed to its logical conclusion.

Such must be the feeling of every discerning reader as he studies the report by the Duke of Bedford and Mr. Spencer Pickering on the chemical relationships of the copper fungicides. The problem is one of very great economic importance. Modern conditions of fruit-growing tend to foster and distribute from country to country the fungi parasitic on fruit trees. On the other hand, the grower is more and more anxious to keep them down; not only do they adversely affect his yield, but they often spoil the looks of his fruit, a very serious matter in modern markets.

The most popular fungicides are the copper compounds, more particularly Bordeaux mixture, a basic salt prepared by adding lime to a solution of copper sulphate. This mixture has been used by fruit and potato growers for a number of years with great success, and has formed the subject of a vast number of papers. Unfortunately few of them are of much value, since it only rarely happens that a man is found to combine an interest in horticultural problems with exact habits of thought. Until recently nothing was known of the composition of Bordeaux mixture, not even the proportions in which the constituents should be mixed to give the best results. Certain American investigators recommended 4 lb. of copper sulphate in fifty gallons of water, and some of the English writers, borrowing not too intelligently in this as in other matters, recommended the same strength, oblivious of the fact that the American gallon is little more than four-fifths of the English

¹ Eleventh Report of the Woburn Experimental Fruit Farm, by the Duke of Bedford, K.G., F.R.S., and Spencer U. Pickering, F.R.S. (The Amalgamated Press, Ltd., 1910.)

gallon. There are several other recipes, but nothing enabling one to decide which is the best. The mode of action is even more obscure; indeed, the whole subject was in a state of confusion until Mr. Pickering took it in hand and began to evolve something like order.

The reaction between copper sulphate and lime is shown to yield four basic sulphates:—(a) $4\text{CuO}, \text{SO}_3$; (b) $5\text{CuO}, \text{SO}_3$; (c) $10\text{CuO}, \text{SO}_3$; (d) $10\text{CuO}, \text{SO}_3, \text{CaO}$; and two other compounds (e) $\text{CuO}, 2\text{CaO}$ (existence doubtful); (f) $\text{CuO}, 3\text{CaO}$. The conditions of the formation of each of these basic sulphates were investigated and a series of the corresponding Bordeaux mixtures prepared.

The properties of the sulphates were studied, and in particular their decomposition under the influence of water and carbonic acid in presence of calcium sulphate or of organic matter, these being the conditions obtaining on the leaf surface. The next problem was to ascertain the function of Bordeaux mixture and so to settle which was the most useful of the possible basic sulphates. These salts are, of course, insoluble and have to be converted into a soluble substance before they can exert a fungicidal action. No evidence could be obtained that the plant leaf or the spore excreted anything that would dissolve an insoluble substance, but it was shown that the carbonic acid of the air decomposed these basic sulphates in accordance with the following reactions:—

The copper sulphate thus liberated constitutes the active part of the mixture. It acts in two ways. It directly poisons the fungus cell developing from the spore. Some of it gets into the leaf, displacing a certain amount of iron and entering into a remarkable combination not yet investigated, which seems so long as it persists to afford the leaf immunity against fungal attacks. Further studies of this remarkable body will be awaited with interest; it will be remembered that Church isolated a pigment *turacin* containing copper from certain genera of the family Muscophagidae, but no such pigment is known in the vegetable kingdom up to the present. But to return: the object of the fungicide is to furnish a steady supply of copper sulphate, and therefore the compound (a) is the most efficient of the series. In the case of (d), the ordinary Bordeaux mixture, a secondary reaction sets in between the calcium carbonate and the copper sulphate which further reduces its efficiency. (a) is, however, physically less suitable than (c). The whole leaf surface of the tree has to be covered with the mixture, and consequently the more bulky the mixture the better; since (c) occupies more than four times the volume of (a) it makes the most economical fungicide in practice. From the fruit-grower's point of view this compound has the further advantage that it can be made on the commercial scale and sent out as a paste ready for use. The paste has been extensively tried in orchards, with results that have completely confirmed the laboratory experiments. Several interesting side-issues were followed up. Some of the compounds in the ordinary Bordeaux mixture and in the so-called soda Bordeaux, obtained by mixing copper sulphate and sodium carbonate, contain copper in the electro-negative condition, i.e. in the acid radical, and were called cupricarbonates; they appear to have no fungicidal action, they combine with cellulose, and slowly decompose to form cuprous oxide.

The report will be found one of the most interesting that has issued from Woburn. E. J. R.

UNDERGROUND TOPOGRAPHY IN IRELAND.

THE exploration of caves has become an athletic pursuit for certain enthusiastic specialists, perhaps as a complement to mountain-climbing. The results, however, have distinct scientific value, when careful plans of the caves are made, and underground waterways are traced. Attention has been directed in these pages to the economic bearing of "spelæology" in the Juras, and the work of the geographer is obviously incomplete, if his streams terminate, as so often happens, in swallow-holes in a limestone area, while others appear freshly on the surface, but may prove to be old friends returning to the upper world. Cave-research is arduous and often dangerous, and the wonder is that such accurate observations are provided for us by men who have to work under cramped conditions, and sometimes liberally immersed in water.

The Royal Irish Academy (Proceedings, vol. xxvii., section B, 1909) has recently issued two geographical memoirs on Irish caves. The first (pp. 183–192, price 6d.) is by Mr. Harold Brodrick, on "The Marble Arch Caves, County Fermanagh: Main Stream Series." The principal cave was explored and described by M. Martel some twelve years ago, with the assistance of the Irish naturalist, Dr. H. Lyster Jameson. Mr. Brodrick, with Dr. C. A. Hill, Mr. R. Lloyd Praeger, of Dublin, and other workers, was able to devote a longer time to the exploration of the district. The training and experience gained by most of the party in Yorkshire enabled them to add many new points to the topography of the area. As Mr. Brodrick remarks, the Marble Arch cave will "probably never become a show-cave, as the climb from the foot of the Great Boulder Chamber to the end of the Pool Chamber Passage is not one to be rashly undertaken." The by-paths of the recent exploration led the adventurers into several difficult places, not to speak of waters, where few will care to follow them. A large-scale map is provided, on which, however, the names used in the text are not always to be found.

The second paper (pp. 235–68, with four plates, price 1s. 6d.), on "The Mitchelstown Caves, County Tipperary," has a wider general interest. The authors are Messrs. C. A. Hill, H. Brodrick, and A. Rule; but Mr. R. Lloyd Praeger took part in the exploration. The New Cave, between Mitchelstown and Cahir, is probably the best-known cave in Ireland; but the plan now given of it seems to be far more accurate than that published by M. Martel, and includes several passages and chambers previously unrecorded. The work may not have been so exciting as that among the unfathomed waterways of Fermanagh, but one and a half miles of cave and passage have been mapped out. A curious point is that the names "Demon Cave" and "Victoria Cave" were found chalked up in some of the unrecorded portions, and these have been adopted in the plan. The names in this plan, by the bye, require one or two corrections to bring them into agreement with the text. The account of the New Cave might have been rendered even more complete by a reference to Prof. Carpenter's paper on its fauna in the *Irish Naturalist* for 1895.

Still more interesting is the description of the smaller Old Cave, which had apparently not been visited by tourists since 1833. The plan now given, covering 479 yards of cave and passage, is the first that has been made.

The clay of the cave-floors, which, as all visitors know, renders them unpleasantly slippery, is described on p. 267 as derived by inwashing from the Old Red Sandstone; but the quartz crystals noted in it, which are so common in the Carboniferous Limestone, and its general character as a *terra rossa*, make it

immensely more probable that it is a residue from solution of the limestone.

The paper is well illustrated, and one photograph shows an "anemolite," or stalactite the growing tip of which has been bent sideways by the action of air-currents.

Mr. Brodrick has also published a general account of the explorations in Fermanagh in the Yorkshire Ramblers' Club Journal. G. A. J. C.

NOTES.

THE following fifteen candidates have been selected by the council of the Royal Society to be recommended for election into the society:—Mr. J. Barcroft, Prof. G. C. Bourne, Prof. A. P. Coleman, Dr. F. A. Dixey, Dr. N. G. Filon, Mr. A. Fowler, Dr. A. E. Garrod, Mr. H. Hardy, Dr. J. A. Harker, Prof. J. T. Hewitt, Prof. B. Hopkinson, Dr. A. Lapworth, Lieut.-Colonel Sir W. B. Leishman, Mr. H. G. Plimmer, and Mr. F. Soddy.

INVITATIONS have been issued to meet the general board of the National Physical Laboratory at the laboratory on Friday, March 18, when the various departments will be open for inspection, and apparatus will be on view.

SIR VICTOR HORSLEY, F.R.S., has been elected a foreign associate of the French Academy of Medicine.

DR. W. F. HUME has been appointed director of the Geological Survey of Egypt.

MR. ANDREW CARNEGIE has offered (the *Times* states) to give a prize of 5000*l.* to the first student of the Carnegie School of Technology at Pittsburg who constructs an aeroplane satisfying certain conditions.

THE Friday evening discourse at the Royal Institution on March 11 will be delivered by Dr. H. Brereton Baker on "Ionisation of Gases and Chemical Change," and on March 18 by Sir J. J. Thomson on "The Dynamics of a Golf Ball."

THE death is reported, at the early age of thirty-three, of Mr. J. F. Ferry, for many years an ornithologist in connection with the Field Museum, Chicago. In collecting for that museum he made expeditions among the islands of the Caribbean Sea and along the coast of the Gulf of Mexico. He also carried out investigations in Arizona for the U.S. Biological Survey, and in the mountains of California for the Smithsonian Institution.

THE following appointments have been made recently by the governing body of the Lister Institute of Preventive Medicine:—Mr. H. R. Dean and Dr. G. H. Macalister, assistant bacteriologists to the institute; Dr. H. McLean, junior assistant in the bio-chemical department; Mr. Ashley Cooper, Jenner memorial research student; Mr. Roland V. Norris, Grocers' Company research student; R. S. G. Paine, research student in the chemical department.

THE annual conversazione of the Selborne Society was held in the theatre and halls of the Civil Service Commission on Friday, February 18. Sir John Cockburn, C.M.G., gave an address on the objects of the society and the aims of its members, while Mr. E. J. Bedford lectured on "Gilbert White and his Associations with Selborne." Among the interesting exhibits was a working model of a pole-lathe still in use for turning bowls in Berkshire, which was made and exhibited by Mr. William Lawrence. The number of microscopes shown amounted to one hundred, and the evening was probably the most successful yet arranged.

THE Geologists' Association is making arrangements for an Easter excursion to north Devon. It is intended that the excursion shall last from March 24 to March 30, and be under the directorship of Messrs. J. G. Hamling and Inkermann Rogers. The official party is to leave Paddington by the 1 p.m. train on March 24 for Barnstaple. On successive days the Upper Culm Measures, the Upper Devonian, the Lower Culm, and the Lower Devonian are to be studied in different districts. Full particulars as to the excursion can be obtained from Mr. Mark Wilks, 47 Upper Clapton Road, London, N.E.

THE Blue Hill Meteorological Observatory, situated near Boston, U.S.A., has just completed an existence of a quarter of a century. Founded and maintained by Prof. A. Lawrence Rotch, detailed measurements of cloud heights and velocities were early conducted, and in 1894 the first meteorological records in the world were obtained with kites at this station. These were extended ten years later with sounding balloons to great heights above the centre of the American continent, and, through the co-operation of M. Teisserenc de Bort, over the Atlantic Ocean (*NATURE*, vol. lxxiii., pp. 54-6, 449-50; vol. lxxx., pp. 219-21). These observations in the free air, like those made elsewhere in the interest of aërology for the International Commission for Scientific Aeronautics, have now become useful to aëronauts and aviators.

PROF. W. KRAUSE, whose death was recently announced from Berlin, at the age of seventy-six, was one of the better known of modern German anatomists. He was a son of the famous Dr. Carl Krause, professor of anatomy in the University of Hanover, who published a remarkable text-book of anatomy—"Handbuch der menschlichen Anatomie"—in 1833. The preparation of the third edition of this work, from 1876 to 1880, constitutes one of the most important contributions made to anatomy by the late Prof. W. Krause. His researches on the terminal organs (end-plates) of motor nerves gained him an early and wide reputation among histologists. Originally professor of anatomy in the University of Göttingen, he went, late in life, to Berlin, where he occupied the position of head of the anatomical laboratories of the University, under the directorship of the veteran anatomist, Prof. Waldeyer.

FEBRUARY was a stormy and unsettled month over the whole of the British Islands, and the total rainfall was large. At Greenwich the mean temperature for the month was 42.1°, which is 2.3° warmer than the average of the previous sixty years; the mean of the day readings was 48°, and the mean of the night readings was 36°. Frost occurred in the screen on seven nights, but on the grass in the open on fifteen nights. The aggregate rainfall at Greenwich was 2.72 inches, which is 1.23 inches more than the average; rain fell every day with three exceptions. February was wetter than any corresponding month during the last ten years. The sun was shining for seventy hours, which is thirteen hours in excess of the average. Cyclonic systems traversed our islands with great frequency during the month, the central areas following a track well to the northward, so that westerly winds greatly predominated. The Meteorological Office, alluding to the violent gale which occurred on Sunday, February 20, mentions that the squalls reached "storm" force in many parts of the country, and "hurricane" force at Southport, Scilly, and Pendennis Castle. The maximum velocity of the wind at Southport was at the rate of more than eighty-five miles an hour, using the new factor for the wind velocity as determined by the Meteorological Office.

THE Royal Meteorological Society held its first meeting out of London on Wednesday, February 23, in the physical laboratory of the Manchester University. Dr. Hopkinson, the Vice-Chancellor, expressed the gratification the University felt at receiving the fellows of the society. He said that the history of the University showed that they were not merely in expression, but in act, interested in this branch of scientific work, as much had been accomplished in meteorology by the work initiated and supported by Dr. Schuster. Dr. A. Schuster also welcomed the society, and said that, although meteorology in itself might be regarded by some as a small part of physical science, yet it was intimately connected with a number of other subjects, especially with one large subject which he thought had received far too little attention in the universities, namely, the whole physics of the globe.

WE learn from *Science* that the board of managers of the National Geographic Society has adopted the following resolutions:—"The National Geographic Society believes that it is of importance to science that tidal, magnetic, and meteorological observations shall be obtained at or in the vicinity of Coats Land during the same period that the British expedition under Captain R. F. Scott, R.N., is making similar observations on the other side of the Antarctic area, 1800 miles distant, and at the same time that this recently discovered land shall be explored. That the society is ready to accept Mr. Peary's proposition that it shall undertake jointly with the Peary Arctic Club an expedition to the Antarctic regions as outlined above, provided that the board of managers, after consultation with the members of the society, finds that the project will receive sufficient financial assistance to warrant the undertaking."

DR. CHARCOT gives in the Paris edition of the *New York Herald* an account of the scientific work accomplished by his recent Antarctic expedition. He says that during the whole duration of the expedition, both while in winter quarters and during the two voyages, the scientific work was carried out unceasingly. During the whole of the voyages oceanographic soundings were taken and dredgings made. At the same time hydrographic and meteorological observations were made, and natural-history studies effected. These were also carried out while in winter quarters. Very complete maps were made of the regions seen from the coasts, and astronomical observations and studies in terrestrial gravitation were carried out at numerous stations. The seismograph was at work in the winter quarters and on Deception Island. Observations in meteorology, atmospheric electricity, and physical oceanography, including numerous soundings, were carried on almost continually while the expedition was in winter quarters.

THE thirty-second annual general meeting of the Institute of Chemistry was held on Tuesday, March 1, Dr. George Beilby, F.R.S., president, in the chair. In moving the adoption of the report of the council, Mr. David Howard alluded especially to the new requirement in the final examination of a useful knowledge of French and German. He believed that this addition would prove of great benefit to chemists, and he knew that it could be left to the examiners to apply the test of this knowledge humanely. They did not want school, commercial, or legal French and German, but a useful knowledge sufficient to enable them to consult technical literature in those languages. Dr. Beilby then delivered his address. He remarked that the institute had undoubtedly influenced the teaching of the universities and colleges, and had endeavoured to encourage the production of men who could not only talk

about chemistry, but were able to apply their knowledge usefully. In moving a vote of thanks for the address, Sir William Ramsay said he was inclined to think that the tendency was to trust too much to the results of examinations. He was of opinion that the aim of the examiners should be to ascertain if the candidates could converse freely and easily on their subject and put it into practice.

A PRIZE of 3000 lire (about 120*l.*) is to be awarded by the section of physical sciences of the Royal Academy of Bologna. The competition is an international one, and the prize is due to a generous donation to the section by a corresponding member, Prof. Elia de Cyon. The object of the competition is to further researches and studies in the subjects which he took up with much success. The subjects of the works submitted for the prize are to have reference particularly to:—(1) the functions of the heart, and especially of the nervous, cardiac, and vaso-motor systems; (2) the functions of the labyrinth of the ear; (3) the functions of the thyroid gland, the hypophysis, and the pineal gland. The works submitted must be of recent date, in the case of the present (the first) competition not prior to March 1, 1909. Memoirs may be written in Latin, Italian, French, German, or English. Competitors may be called upon to repeat their experiments in the presence of the three members of the adjudicating committee. The prize will not be divided, and may not be conferred more than once upon the same person. The section of physical sciences reserves the right to publish the successful paper in its Transactions. No member of the section is eligible for the competition. Further particulars may be obtained from Il Segretario, Classe di Scienze Fisiche, R. Accademia delle Scienze, Bologna.

In our issue for December 23 last we recorded Mr. Otto Beit's munificent gift of 215,000*l.* for the foundation and endowment of medical research scholarships. The trustee of the fund met on February 23, and awarded the first set of the fellowships. Seventy applications were received—fifty-eight from England, three from Scotland, one from Ireland, one from Wales, and seven from abroad. The following fellows were elected, and were authorised to proceed with the researches mentioned after their names:—Mr. G. H. Drew, the zoological distribution of cancer and a systematic study of an experimental character on the mode of origin of neoplasms (tumours); Dr. F. W. Edridge-Green, various problems connected with vision and colour-vision, especially in relation to the correct reading of signals on land and sea; Mr. E. Hindle, the morphology and treatment of protozoic blood parasites, especially *Spirochaeta duttoni* and trypanosomiasis (sleeping sickness); Dr. T. Lewis, the mechanism of irregularities of the heart; Dr. G. C. McKay Mathison, (a) the nervous control of respiration, and (b) the effect on respiration of changes in the chemical composition of the blood; (c) the mechanism of biliary secretion and its general effect on digestive processes; Dr. Otto May, clinical and experimental research on the lesions of peripheral nerves; Mr. E. Mellanby, the significance of the large excretion of creatin in cancer of the liver and its diminished excretion in cirrhosis of the liver, &c.; Dr. F. P. F. Ransom, the mode of action of caffeine, theobromine, and allied substances on the muscular and nervous systems; Dr. S. Russ, the association of radio-activity with cancer; Dr. Ida Smedley, the processes involved in the formation of fat in the organism. The next election of fellows will be held about December 15 next. All inquiries should be addressed to the honorary secretary, Beit Memorial Fellowships for Medical Research, 35 Clarges Street, Piccadilly, London, W.

THE death is announced of M. Philippe Thomas, the eminent and enthusiastic geologist who did important pioneer work in Tunis and Algeria. Born at Duerné (Rhône) in 1843, he entered the veterinary school at Alfort in 1860, and became a prominent member of the French army veterinary service, from which he retired about nine years ago. From his earliest youth he was deeply interested in geology, and when his official appointment took him to Algeria he devoted his scanty leisure to the study and collection of the rocks and fossils of that country, and was especially eager in the search for evidence of primitive man. During twenty years he published a series of notes and papers on subjects ranging from man and Tertiary vertebrates to the stratigraphy of the region. In 1884 he was chosen by the Minister of Public Instruction to join the well-known scientific mission to Tunis as one of the geologists, and there he had ample scope for the exercise of his abilities. He discovered the immense deposits of phosphatic chalk, which have subsequently proved of so great economic importance to Tunis. He amassed material for an exhaustive description of the geology of the country, and his later years were occupied with its preparation for publication. Unfortunately, only two parts of this work appeared, and the third part, dealing especially with the phosphatic deposits, remained unfinished at the time of the author's death.

AN appreciative account of the scientific work of Mr. Edward Saunders, F.R.S., who died, we regret to learn, on February 6, in his sixty-second year, appears in the March number of the *Entomologist's Monthly Magazine*, of which he was an editor. From this notice we extract the following particulars of Mr. Saunders's career:—Edward Saunders devoted himself first to the Coleoptera, but acquired also considerable familiarity with entomology in general, and with several other of the "systematic" sciences, such as botany and conchology. At the age of sixteen he published a paper in the first volume of the *Entomologist's Monthly Magazine* on Coleoptera at Lowestoft, and was afterwards for some years mainly occupied in studying the Buprestidæ of the world. A succession of notes, descriptions, revisions of particular collections, groups, &c., bearing on this subject were communicated by him to the Transactions of the Entomological Society from 1866 to 1869; in 1870 he published a "Catalogue of the Species contained in the Genus *Buprestis*, Linn.," and in 1871 his "Catalogue Buprestidarum Synonymicus et Systematicus," a work the importance of which was immediately recognised. From 1872 to 1874 he continued his work on this group, describing several new genera and more than a hundred new species, and at the same time began to issue a long series of notes on British Hemiptera, which were followed in 1875-6 by a synopsis, in three parts, of the British Hemiptera-Heteroptera, and this again by a large illustrated volume, his well-known "Hemiptera-Heteroptera of the British Isles," which was published in 1892. Concurrently with this important mass of work on two distinct orders of insects he began to attack a third group, the Aculeate Hymenoptera, to which he gradually transferred his chief attention. For the rest of his life the Aculeates (especially the British species) became his favourite study, and he ultimately became, not merely the foremost, but, it may almost be said, the final authority upon the latter. His grand work "The Hymenoptera-Aculeata of the British Isles" (1896) is one of the few without which no serious hymenopterist thinks his working library complete. Saunders became a Fellow of the Entomological Society in 1865, served as treasurer from 1880 to 1890, and was a vice-president in no fewer than five sessions,

viz. in 1874, 1899, 1901, 1906, and 1907. Though he never actually held the presidency, it is scarcely a secret that he would more than once have been elected to it unanimously if he could have been persuaded to accept a post the duties of which he felt unequal (physically) to discharge so completely as he would have wished. He entered the Linnean Society in 1869, and about that time contributed at least three papers to its journal. Long after, in 1890, he published in the same journal an exceedingly careful and interesting paper on the tongues, &c., of bees, with beautiful illustrations, drawn by his brother, Mr. G. S. Saunders, from microscopic preparations made by Mr. Enock. His election in 1902 to the honour of fellowship in the Royal Society was not only highly gratifying to himself and his personal friends, but to all who saw in it a recognition of systematic entomology, treated as Saunders treated it as no mere idle dilettantism, but a genuine branch of science.

ONE of the features of the fauna of continental Africa is the absence of flying-foxes of the typical genus *Pteropus*, this absence extending also to the island of Zanzibar. On the other hand, representatives of these bats occur in Madagascar and the Mascarene, Comoro, and Seychelles group. Recently, specimens of a new species of flying-fox have been obtained from the island of Pemba, which lies to the north of Zanzibar at a distance of only about 37½ miles from the mainland. That the genus should be found so close to the African continent, and yet should never have reached the same, is very remarkable, especially when the long interval between the Comoros and Seychelles, on the one hand, and the Andamans and Ceylon, on the other, is borne in mind. The Pemba species, which is described by Dr. P. Matschie in the *Sitzungsberichte Ges. naturfor. Freunde*, Berlin, 1909, p. 482, belongs to the short-nosed group of the genus distinguished as *Spectrum*, and has been named *Pteropus voeltzkowi*.

IN vol. xxxii., part i., of Notes from the Leyden Museum, Dr. F. A. Jentink describes a new bat from Java, and at the same time proposes the name *Chrysopteron* for the Celebesian *Cerivoula weberi* and the new species, which are regarded as constituting a genus by themselves. The typical plantain-bats of the genus *Cerivoula* (*Kerivoula*) are characterised by the normal form of the upper canines and the tricuspid first pair of lower incisors; a second genus, *Phoniscus*, as represented by *P. atrox* of Sumatra, differs by the elongation and compression of the shaft of the upper canines and the quadricuspid first lower incisors, while the new genus is characterised by the presence of four cusps to both first and second lower incisors. It may be pointed out that *Chrysopteron*, which includes the Celebesian *C. weberi* and the Javan *C. bartelsi*, is practically identical with the much earlier name *Chrysoptera*.

CONSIDERABLE interest attaches to two papers, by Mr. Knud Andersen, in the January number of the *Annals and Magazine of Natural History* on the African fruit-bats of the *Epomophorus* group. Hitherto, with the exception of *Hypsignathus monstrosus*, all these bats have been very generally included in the single genus *Epomophorus*. The author shows, however, that the Angolan *E. anchietae*, on account of possessing $\frac{1}{2}$ pairs of cheek-teeth (in place of the usual $\frac{3}{4}$), the great width of the palate, and other cranial characters, is entitled to rank as a genus by itself, for which the name *Plerotes* is proposed, this genus being intermediate between *Rousettus* (cheek-teeth $\frac{1}{2}$) and *Epomophorus*. Next to *Plerotes* comes the genus *Epomops*, as represented by *E. franqueti* and *E. comptus*, in which

the muzzle and palate are also wide, although somewhat less so than in the Angolan genus, the hind portion of the palate retaining the flattened form characteristic of *Rousettus* and its allies. In *Epomophorus*, on the other hand, the palate is narrow and deeply hollowed out behind, thereby differing from the same region in all other members of the fruit-eating group. Lastly, we have the genus *Micropteropus*, characterised by the extreme shortness of the skull, which approximates in this respect to that of *Cynopterus*.

A SHORT paper on the gametophytes of the orchid, *Calopogon pulchellus*, is contributed by Miss L. Pace to the *Botanical Gazette* (August, 1909), which adds to the gradually accumulating information regarding developmental details of the megasporangium. The formation of a single sporogenous cell, as generally observed, and absence of any parietal cells, coincides with the typical routine in orchids, but anomalous conditions appeared in several ovules where two mother-cells were found either contiguous or with nucellar tissue lying between. The figures are suggestive of two archesporia side by side, but the ultimate fate of these cells was not determined. Four megaspores were usually formed, although dividing walls between them were wanting; owing to disintegration of three of the nuclei, the chalazal nucleus alone persisted to become the nucleus of the embryo sac. Evidence in favour of double fertilisation is adduced.

A BROCHURE dealing with the cultivation of fibre plants in India has been issued as Bulletin No. 15 of the Agricultural Research Institute, Pusa. There is a noteworthy division into peasants' crops, capitalists' crops, and fibres worth experimental attention. The first category comprises jute, *Hibiscus cannabinus*, *Crotalaria juncea*, and cocoa-nut; the second includes rhea, agave, *Sansevieria*, and flax, while plantain and sida fall into the third category. The cultivation of jute has not spread to any appreciable extent beyond the provinces of Bengal and Assam. *Hibiscus cannabinus* is preferred to jute in certain regions, notably the Vizagapatam and Kistna districts in Madras, because it requires less water. Sann hemp, *Crotalaria juncea*, thrives in districts of moderate rainfall; there is an established industry in the fibre in parts of the Central and United Provinces and of Assam, but the plant is more frequently grown to supply green manure or fodder.

THE principal article in *Symons's Meteorological Magazine* for February is devoted to the "Proposed Imperial Meteorological Organisation," discussed at an informal conference of meteorologists at the Winnipeg meeting of the British Association last year. The circular letter drawn up by the committee then appointed for transmission to meteorological authorities of the British Empire, inviting cooperation in contributing data on a common plan for publication by a central agency, is reprinted, and states that, primarily, information is required as to pressure, temperature and rainfall, and their fluctuations from the normal, and it is suggested that the form adopted by the Solar Commission of the International Meteorological Committee, whose headquarters at the present time are in London, in connection with the Solar Physics Observatory, should be followed. Monthly tables relating to the climate of different parts of the British Empire have appeared in *Symons's Meteorological Magazine* for many years; the editor heartily welcomes the establishment of a more general system, under official auspices; at the same time, he does not think that a new system of expressing meteorological observations is desirable.

NO. 2105, VOL. 83]

The meeting at Winnipeg expressed an opinion in favour of the use of absolute units for pressure and temperature; for the present, however, the circular states, it is not proposed to ask the various authorities to come to any final decision upon the point.

FROM the February Bulletin of the American Mathematical Society we learn that the Göttingen Academy of Sciences has awarded 5*l.* to Dr. A. Wieferich, of Münster who has shown that the equation $x^p + y^p = z^p$ cannot be solved in terms of positive integers, not multiples of p , if $2^p - 2$ is not divisible by p^2 . The announcement is followed by the comment:—"This surprisingly simple result represents the first advance, since the time of Kummer, in the proof of the last Fermat theorem."

IN the *Annals of Mathematics* (October, 1909) Mr. Frank Gilman discusses the theory of floating tubes as applied to the measurement of currents in open channels of water. The method was first described by Mr. T. A. Mann in a paper communicated to the Royal Society in 1779, and was used by R. T. Krajenheff in Holland (1813), M. de Buffon on the Tiber (1821), Destrem on the Neva (1835), and Francis in America (1852). The tubes ranged from 6 feet to 10 feet in length, and were allowed to float down the stream over a measured course of 70 feet. Other experiments mentioned are those of Captain Cunningham in India (1874-9), of which a detailed discussion is given in the paper, M. A. Graëff (1883), and Messrs. Humphreys and Abbot on the Mississippi River (1851-76).

THE University of Illinois has established an engineering experiment station to carry on investigations along various lines of engineering. Especial attention has been paid to problems bearing on fuel, and the two last bulletins issued deal with this subject. The first of these, by J. M. Snodgrass, is on fuel tests with house-heating boilers. Central heating by steam is more common in the United States than in this country, but the figures given are not without interest over here. The fuels used, of which complete analyses are given, included anthracite, gas coke, bituminous coal, and briquettes of various kinds. The tests were very complete, and deal with questions of efficiency, cleanliness, cost of control, smoke, and soot. The boiler efficiencies determined varied from 45 to 66 per cent. The experimental data are discussed in a very complete manner, especially from the cost point of view. The only point open to criticism is the unnecessary number of significant figures in the experimental results. Thus we find the calorific value of a coal given as 14,229 B.T.U. per lb., and boiler efficiencies are given to 0.01 per cent. Three significant figures in the calorific value probably represent the limit of accuracy attainable in such experiments when the sampling difficulties are taken into account; an accuracy of 1 in 14,000 in a thermal measurement is certainly unattainable.

THE second bulletin, by S. W. Parr and Percy Barker, deals with the occluded gases in coal. These experiments are of practical importance in two directions, first as bearing on the spontaneous combustion of coal, and secondly as showing how to prevent deterioration of stored coal. Coal commences to give off inflammable gases as soon as it is mined, and at the same time absorbs oxygen from the air, both these changes taking place with greater rapidity the finer the state of division of the coal, and both being almost entirely suppressed when the coal is submerged in water.

THE *Zeitschrift für physikalische Chemie* (January 25) contains a paper, by J. T. Barker, on the determination of the vapour pressures of toluene, naphthalene, and

benzene at temperatures ranging from -78° C. to 25.8° C. At the lower temperatures the statical method is not sufficiently exact, and hence the vapour pressures were measured by saturating pure oxygen, prepared electrolytically, with the vapour of the substance, the latter being maintained at a constant temperature. The amount of vapour carried away by the oxygen was determined by combustion, full details being given of the precautions necessary for exact working. The method was shown to be capable of measuring vapour pressures down to 0.005 mm. of mercury. The experimental results were compared with Nernst's formula for the calculation of vapour-pressure curves, and for toluene, naphthalene, and benzene; the agreement was found to be satisfactory.

AN interesting article appears in *Engineering* for February 25 giving particulars of a new shrinking and tempering shop for guns at Woolwich Arsenal. Modern built-up guns have steel tubes and liners which require oil-hardening, and as these guns are sometimes of great length, it will be understood that adequate means must be provided for lifting the guns to considerable heights. It was decided that the new building should be 300 feet long in the clear (the first part to be constructed being 150 feet), 60 feet wide, and 90 feet high from the floor-level to the gantry rail. It was also stipulated that an electro-hydraulic travelling crane should be installed capable of lifting 120 tons, and of travelling with its load at a speed of 75 feet per minute, the speed of the cross-traverse under similar conditions being 35 feet per minute. Another requirement of this crane is ability to lower a weight of 60 tons at a speed of 500 feet per minute, this being of great importance on account of the necessity of dipping the guns rapidly into the oil in the process of hardening. Two deep pits, each 11 feet in diameter, are provided for oil-hardening tanks; also one shallower overflow pit, a driving pit 18 feet in diameter with an anvil bottom, and a shrinking pit.

MESSRS. CASSELL AND COMPANY, LTD., have commenced the publication, in fortnightly parts, sold at one shilling net each, of Mr. Richard Kearton's "Nature Pictures." The illustrations are beautifully reproduced, and are accompanied by descriptive text. The work will be completed in twenty-four parts, and we propose to review it when the serial publication is complete.

A SECOND edition of an essay entitled "The Finest Walk in the World," by Miss B. E. Baughan, which originally appeared in the *Spectator*, and was published recently in pamphlet form with numerous illustrations, has been issued by Messrs. Whitcombe and Tombs, Ltd., of Addle Hill, Carter Lane, London. The walk, some thirty-three miles in length, is in the neighbourhood of the celebrated Milford Sound, in the south-west corner of New Zealand. Judging from the beautifully reproduced photographs and the enthusiastic descriptive text which accompanies them, the walk must reveal a succession of panoramic views of Nature at her loveliest.

THE annual report of the board of regents of the Smithsonian Institution, showing the operations, expenditures, and condition of the institution for the year ending June 30, 1908, has been received. As usual, the general appendix of the volume, running to some 684 pages, will make the widest appeal to readers. It contains a representative selection of papers and addresses by distinguished men of science dealing with notable current scientific researches. Some of these are translations into English from German, French, and Swedish publications, others have appeared in *NATURE* from time to time, and the remainder

are from American and British authors, some being original, while others are reprints. The following contributions may be mentioned:—Sir Joseph Thomson's Adamson lecture to the University of Manchester, on the light thrown by recent investigations in electricity on the relation between matter and ether; Prof. J. W. Gregory's contribution to the Congrès géologique international, Mexico, 1906, on climatic variations: their extent and causes; Prof. J. Joly's address to the geological section of the British Association at Dublin in 1908, on uranium and geology; Captain H. G. Lyons's lecture to the Royal Geographical Society, on some geographical aspects of the Nile; Prof. Ronald Ross's address to the Oxford Medical Society in 1906, on malaria in Greece; and Prof. Silvanus P. Thompson's Kelvin lecture of 1908 (abridged and revised by the author), on the life and work of Lord Kelvin.

OUR ASTRONOMICAL COLUMN.

ASTRONOMICAL OCCURRENCES IN MARCH:—

- March 3. 12h. cm. Venus stationary.
 7. oh. 39m. Uranus in conjunction with the Moon (Uranus $3^{\circ} 34' N.$).
 8. 9h. 17m. Venus in conjunction with the Moon (Venus $11^{\circ} 52' N.$).
 10. 6h. om. Vesta in conjunction with the Moon (Vesta $1^{\circ} 9' N.$).
 13. 2h. 45m. Saturn in conjunction with the Moon (Saturn $0^{\circ} 58' N.$).
 15. 19h. 17m. Mars in conjunction with the Moon (Mars $1^{\circ} 16' N.$).
 18. 17h. om. Venus at greatest brilliancy.
 25. 18h. 21m. Jupiter in conjunction with the Moon (Jupiter $2^{\circ} 31' S.$).
 30. 18h. om. Jupiter at opposition to the Sun.

COMET 1910a.—In these columns last week reference was made to two drawings, of comet 1910a, which are now reproduced from the *Comptes rendus* (No. 7, p. 370, February 14). They were made by M. Esclançon, and illustrate the remarkable change which took place in the appearance of the comet's head between January 22 and 30.

January 22.

January 30.

M. Esclançon points out that such apparent changes may be produced in two ways:—(1) by actual changes in the comet itself; (2) or by the different angles at which it is presented to the observer. While great real changes undoubtedly took place in comet 1910a, a certain proportion of the apparent change can be explained by the different aspect, for on January 22 the angle made by the tail with the line-of-sight (comet-earth) was 96° , whilst on January 30 it was 133° ; but, apart from this, there was a real change in brightness and in the condensation of the nucleus consequent upon the comet's recession from the sun; on the former date its distance was about 0.25, on the latter about 0.55, astronomical unit.

M. J. Comas Sola also made a special study of the figure of the comet, and gives his results in the same

number of the *Comptes rendus*. He remarks that the tail was always bifurcated, as though the nucleus formed a screen to the repulsive force acting on the vapours, and at its greatest length extended to a distance of 50° . Photographs taken at the Fabra Observatory show the details very well, but are not suitable for reproduction. Special attention was paid to the secondary tail on the left of the comet, which was much fainter than the primary, and extended to the opposite side, that is, towards the sun. This tail was *concave* to the direction of the motion, and it is this point that M. Sola discusses. He attributes the concave form to the differential action of the gravitational forces of the sun and the nucleus and the repulsive action emanating from the sun. The greater number of particles are repelled and form the principal tail, but others, depending upon their nature, will not be driven away entirely, and will become attracted towards the sun. The finest of these will be disseminated into space, but the heavier ones will, in falling towards the sun, be attracted by the nucleus, and thus produce the observed form concave relatively to the comet's motion; those falling into the nucleus will be again expelled, but others of which the velocity sunwards is too great will rush past the nucleus and form the fan seen on the side of the head nearer the sun. This hypothesis admits of two tests:—(1) before perihelion the concavity should not precede the nucleus; (2) spectroscopic investigation should show the two tails, at a distance from the nucleus, to differ chemically. M. Sola gives a formula by which the acceleration of the different particles might be computed on the assumption that the forces he assumes are all active, but the photographs of comet 1910a do not permit of its application.

FIREBALL OF FEBRUARY 17.—Mr. W. F. Denning writes:—"A considerable number of reports have been received concerning the appearance of this brilliant object. It was seen so far east as in Essex and Kent, and observers in Gloucestershire, Somerset, Devon, and Glamorgan witnessed the descent of the fireball under a more brilliant aspect. The long endurance of the trail was one of the most noteworthy features, and reminds us of the remarkable meteor of February 22, 1909, which left a streak for three hours.

"From the best observations it appears that the fireball of February 17 last descended in a nearly vertical path over a point about twenty miles north-west of Land's End, Cornwall. That its height was approximately eighty-eight to forty-six miles appears very probable, but observations would be valuable from Cornwall and the south coast of Ireland.

"To have created so brilliant an effect in the evening twilight the meteor must have been one of the very largest type, and the shower in Auriga from which it was presumably directed is one of extremely interesting character. Meteors of great size and startling brilliancy are more frequent in the early evening than at any other period of the night, and this is a circumstance to which the writer has several times directed attention."

It is reported that a brilliant meteor, as bright as Venus, was seen from many parts of Yorkshire soon after sunset on Tuesday last, March 1.

HALLEY'S COMET.—In an article on Halley's comet which appeared in the *Times* of February 24, the writer states that the comet is likely to be at its best, as a display, during the last ten days of May, when it will be an evening star and near to the earth. He also suggests that between March 11 and April 24 the comet will probably be unobservable, being too near the sun as seen from the earth. On the latter date it should become visible as a morning star, rising just before dawn; but while its intrinsic light will then be nearly at its maximum, its apparent brilliancy will suffer on account of the distance from the earth. After the transit on May 18, the comet will again become an evening star, and, being then much nearer the earth, should be seen at its best. During the transit Mr. Evershed is hoping to employ both heliograph and spectroheliograph at the Kodaikanal Observatory to obtain records of the comet's nucleus. That this contains a large amount of solid matter is rendered probable by the endurance of the comet for at least 2000 years; simple vapour would scarcely hold together for so long, and

could not be expected to disseminate and lose entirely the amount of matter that has been poured forth by Halley's comet even during its known career. A photograph taken at Greenwich Observatory on January 30 showed a fairly defined nucleus surrounded by a large diffused coma, and a very faint tail.

PIDOUX'S COMET, 1910b.—No further official news of the comet discovered by M. Pidoux at Geneva on February 20 is to hand, nor had any further observations been reported to the *Astronomische Nachrichten* up to February 25; but according to a Geneva correspondent of the *Daily Chronicle* M. Pidoux discovered the new comet photographically whilst photographing Halley's comet, and confirmed the discovery visually. He says the new comet is **V**-shaped, and travelling at a great speed in a south-west direction; also that it is brightening, and, given good weather, should become a naked-eye object in a few days. No magnitude is mentioned.

A NAKED-EYE SUN-SPOT GROUP.—A remarkable group of spots has been observed on the solar disc during the past fortnight. Following a pair of spots of moderate size, a small spot was seen to come round the eastern limb on February 17, and on February 19 developed into a group. This group increased in numbers and extent until, on February 23, the length of the affected area, measured along the greatest diameter, was about one-seventh of the solar diameter, roughly 120,000 miles. On March 1 most of the group had passed over the western limb, and there was a low bank of prominence matter, seen in the C line of hydrogen, lying above its position on the limb. The visual observations at the Solar Physics Observatory, South Kensington, showed that a little to the north of the spot disturbance there was a bright trifurcated prominence on the limb, which changed its form considerably between 10 a.m. and 1 p.m. Mr. J. H. Elgie reports having seen the above spot group with the naked eye on February 25.

THE BRENNAN MONO-RAIL SYSTEM.

A LARGE company of engineers and others interested, including representatives of the Admiralty and of the War Office, assembled at the Brennan Torpedo Works, near Chatham, on Friday, February 25, to witness a demonstration of Mr. Brennan's mono-rail vehicle. The vehicle shown, which is the first of its kind, has been designed for rough military purposes, not for high speeds, and the trials on this occasion were intended to show its adaptability for this kind of work. A general description of the car and the experimental track appeared on p. 79 of our issue for November 18, 1909, to which we may refer our readers, supplemented with the illustration now shown of the vehicle standing on one of the sharp curves. In this illustration may be noticed the radiators for cooling the circulating water required for the petrol motors, these radiators being secured to the front of the machinery cab; the front bowie with its two wheels, the rear wheel being driven by side rods and balanced cranks from one of the two electromotors; also one of the side chocks, on which the car may rest when required for unloading or other purposes. There is a chock on each side of the car. Mr. Brennan is the centre figure in the machinery cab.

The car first made its appearance from the pier, carrying a number of large packing cases and three or four men, and was brought to rest. Then, running on to the circular track of 105 feet radius, the speed was gradually accelerated to twenty miles per hour, the car inclining inwards automatically so as to counteract the effect of centrifugal force. It is of interest to note that the load was simply laid on the flat platform of the car, without being secured in any way, and that there was not the slightest tendency to disturb the position of any of the packing cases while on the curve, thus showing the perfect balance maintained by the gyroscopes. While stopping on the curve, the angle of heel gradually diminished, and the car platform was level on rest being attained.

The operation of unloading in the field was then shown. While the normal action of the gyroscopes is to maintain

the car platform level, the driver can exercise control so as to cause the platform to incline to either one side or the other. With the car at rest on the curve, some packing blocks were laid on the ground reaching to within about a foot of the chock on one side of the car. The driver then inclined the car so that the chock rested on the packing blocks; some planks were laid resting on the ground at one end and against the car platform at the other, so as to extend the inclined plane of the platform down to ground-level. The packing cases were then easily shoved off without the assistance of any tackle whatever. On unloading being completed, the driver caused the car to recover level immediately. Mr. Brennan has not yet published a complete description of the mechanism for bringing the gyroscopes back to their central position, certain patents having been applied for and not yet granted.

We then had an opportunity of taking a run round the circle. All passengers stood, and, despite the fact that there was nothing to take hold of, perfect steadiness of

THE FUEL QUESTION IN THE UNITED STATES.

AN important department of the United States Geological Survey is that devoted to fuel. More than 400,000,000 tons of coal, valued at above 106,000,000l., were raised in 1908, nearly the whole of which was consumed in the country, and this department has made numerous researches as to the best methods of utilising this coal. The information acquired is published from time to time in the form of bulletins, most of which are supplied free or at a nominal cost. Four bulletins recently issued, Nos. 373, 382, 383, and 385, may be taken as indicating the scope of the work done. They are entitled "The Smokeless Combustion of Coal in Boiler Plants," by D. T. Randall and H. W. Weeks; "The Effect of Oxygen in Coal," by D. White; "Notes on Explosive Mine Gases and Dusts," by R. T. Chamberlin; and "Briquetting Tests at the United States Fuel-testing Plant, Norfolk, Virginia, 1907-8," by C. L. Wright. The paper on

The Brennan Mono-Rail Vehicle.

equilibrium was experienced by everyone. The angle of heel inwards we estimated to be about 10 degrees on this trip. An exhibition of the vehicle taking sharp curves followed, the minimum radius being 35 feet, after which we had a trip at high speed down the straight portion of the track and back again. Complete success attended all the trials, and Mr. Brennan is to be heartily congratulated on the results.

From our previous description of the track it will be understood that its simplicity renders it very suitable for military purposes. The short cross-sleepers are simply laid on the ground without ballast, and we noted on this visit that, at one part of the straight line, longitudinal sleepers had been used. At the factory entrance a short part of the line is flush with the surface of the macadam, illustrating the value of the system for tramway work. It is intended to put in hand one or more trailers to be coupled to the present vehicle, in order to show the practicability of running such vehicles on trains.

briquetting is chiefly of interest to the mine-owners and coal-users of Virginia, although the summary of the recent literature on briquetting possesses a wider value. The work described by R. T. Chamberlin in the memoir on explosive mine gases and dusts had only just commenced when, in December, 1907, a series of unusually disastrous explosions took place in the Naomi, Monogah, and Darr mines of Pennsylvania and West Virginia. This led to a diversion of the original inquiry, the gas and dust concerned in these explosions being subjected to a detailed examination. Special attention was given to the part played by the methane evolved from the coal in the production of these explosions, this gas being more rapidly evolved the finer the state of division of the coal. After this emission of methane had gone on for some time the dust was less readily ignited, and experimental evidence is given showing that the fresh dust is more dangerous than old dust.

The memoir by Mr. D. White, on the effect of oxygen

in coal, proves, from the calorimetric point of view, that high oxygen is practically equivalent to high ash. It is also shown that the ratio of hydrogen to oxygen is the best measure of the coking efficiency of the coal, and the effect of the oxygen on the weathering of the coal is also discussed.

The bulletin by Messrs. D. T. Randall and H. W. Weeks, on the smokeless combustion of coal in boiler plants, is of especial interest in the United States, where the regulations against the production of smoke are severe, and strictly enforced. Between 400 and 500 steam plants in thirteen of the larger cities were visited, the data from 285 plants being made use of in this report. The general conclusion is that the smokeless combustion of bituminous coal is possible, and there are many types of furnaces and stokers that are operated smokelessly. The guiding principle is that stokers or furnaces must be set so that combustion is complete before the gases strike the heating surface of the boiler. The plant must be designed for the type of coal it has to burn; no one type of stoker is equally valuable for burning all kinds of fuel. It is worthy of note that, among the numerous stokers described, no mention is made of boilers using powdered fuel, a type particularly well adapted for the smokeless combustion of bituminous coal. The amount of experimental work given is very large, no fewer than fifty-seven tables of results accompanying the text. It is a work which should be in the hands of every engineer responsible for a steam plant. At the end of the bulletin is a bibliography of the survey publications on coal and fuel testing, and also of publications on smoke abatement.

THE SCIENTIFIC REPORTS OF THE LOCAL GOVERNMENT BOARD.¹

WHEN science as a whole is neglected by our Government, it is satisfactory to find that one Government Department at least is alive to the value of scientific research, and is able by annual grants to investigators to assist research and to produce the admirable work contained in the reports under review. It may be hoped, apart from other considerations, that the example of the Local Government Board may serve a useful purpose in encouraging similar work by other Government Departments. These reports of the Medical Officer of the Board are now being issued much earlier than previously, a fact of moment, for the practical value of a research is often diminished by delay in publication.

Dr. Andrewes furnishes a second report on the bacteria of sewer air. He finds the bile-salt neutral red lactose agar medium of McConkey well fitted for the detection of bacteria belonging to the *B. coli* group. In the drain air of a large public institution and of a private dwelling sewage bacteria can be readily demonstrated, but their presence is of a highly intermittent character. The determining cause of the access of sewage bacteria to drain air appears to be droplet contamination from splashing. Dr. Andrewes and Dr. Horder have continued observations on the defences of the body against the pyogenic cocci, commenced last year by Drs. Andrewes and Gordon, and their joint report contains matter of much interest.

In view of outbreaks of cerebro-spinal fever, Drs. Gordon and Horder investigated the relative efficacy of the various anti-meningococcus sera on the market; the sera tested on animals possessed practically no curative or prophylactic value. Treatment with a vaccine, however, gave some promising results. It is to be noted that Flexner and Jobling have obtained very encouraging results in the treatment of epidemic cerebro-spinal fever in man with anti-meningococcus serum.

Dr. Savage submits reports dealing with mastitis in cows ("garget"). Some 70-75 per cent. of the cases are associated with a streptococcus having special characteristics, and termed the *S. mastitidis*; but it is significant, and throws doubt on the specificity of the organism, that the same streptococcus was found in milk from unaffected quarters of the udder. The explanation may be that, as in other microbial diseases, the organism becomes pathogenic

only under special conditions. The streptococci present in cases of human sore throat were also investigated, and were found to be of the *S. anginosus* type.

These two streptococci, morphologically and culturally, are indistinguishable, but show marked differences in their pathogenicity on animals. Thus the mastitis variety is non-virulent to mice and other rodents, but is capable of inducing a mastitis in goats; the anginosus variety, on the other hand, is virulent to mice, but fails to induce mastitis in goats. Dr. Savage therefore suggests that it may be possible to determine whether streptococcal outbreaks of human throat disease are due to milk by the capacity of the streptococci of the human disease to cause mastitis in goats by infection of the teats.

Dr. Savage has also continued his investigations on the cultural reactions and on the presence of bacilli of the Gartner group in the intestinal tract of animals, and in a second report discusses the presence of paratyphoid bacilli in man. It is pointed out that the hog-cholera bacilli are indistinguishable from paratyphoid types, and the suggestion of a connection between paratyphoid fever in man and the bacilli so frequently found in cases of swine fever is an interesting hypothesis, but the balance of evidence at present available seems to be distinctly opposed to any ætiological relationship. Most cases of paratyphoid fever in man are probably associated with specifically contaminated food, but the precise paths of infection cannot yet be said to have been determined.

Reports are contributed by Dr. Sidney Martin on the toxic products of streptococci. The first deals with the pathogenicity and toxins of the streptococcus (*S. faecalis*), so common in the intestinal contents. Injected intravenously into rabbits, this organism produces vegetative endocarditis of the mitral valve of the heart; this may have some bearing on the ætiology of acute rheumatism. The endotoxin on inoculation produces fall of temperature and great bodily weakness.

In the second the mode of growth and toxic products of the streptococcus (*S. pyogenes*) of suppuration are investigated.

The occurrence of "carrier" cases in relation with enteric fever is the subject of a memorandum by Dr. Theodore Thomson and Dr. Ledingham. The problem of "carrier" cases, i.e. individuals in whom the typhoid bacilli persist for long periods after an attack of enteric fever, is a difficult and serious one. Treatment with vaccines and with sour milk have failed to eliminate the bacilli from cases on which they have been tried.

A very important report on the prevalence and sources of tubercle bacilli in cows' milk is contributed by Prof. Delépine. The conclusions are based on an examination of 5320 samples, and 474, or 8.9 per cent., proved to be tuberculous. Various administrative measures are discussed for the eradication of bovine tuberculosis. Details of experiments on the effect of the storage of glycerinated vaccine lymph at temperatures below the freezing point are contributed by Dr. Blaxall and Mr. Fremlin. Cold storage at -5° C. for six months in no way diminishes the activity of the lymph, and for two years only brought about a reduction in activity of about 2 per cent.

This necessarily brief survey of the contents of these volumes may, it is to be hoped, direct attention to the important researches carried out for the Local Government Board, and prevent the papers from being overlooked by those who are carrying out work in the same fields.

R. T. HEWLETT.

SCIENTIFIC ACTIVITY IN NEW ZEALAND.

THE Philosophical Institute of Canterbury, New Zealand, is one of several very active scientific societies in Australasia. The annual report for the year 1909, presented to the annual meeting held last December, is a record of the continued success of the institute in its scientific undertakings. During the year the publication of the results of the expedition to the sub-Antarctic islands of New Zealand was steadily proceeded with under the editorship of Dr. C. Chilton. The reports upon the work will consist of two quarto volumes of about 400 pages each and will be illustrated with numerous plates (some coloured), photographs, and text-figures; they will

¹ Thirty-seventh and Thirty-eighth Annual Reports of the Local Government Board, 1907-8 and 1908-9. Supplements containing the Reports of the Medical Officer for 1907-8 and 1908-9.

accompanied by a large coloured map of the Antarctic and sub-Antarctic regions, showing the ocean depths as ascertained by recent expeditions.

Valuable scientific and economic work in botany has been carried on by Dr. Cockayne during the past two years. Although a great deal has been done in the way of establishing sanctuaries and national parks in order that the native fauna may be preserved for all time, the importance of placing on record their present ecological condition can hardly be overestimated. It is hoped that at some early date the Government may see its way to authorise Dr. Cockayne to proceed further with the botanical survey of the Dominion.

Largely owing to the representations of the institute, combined with those of the Otago Institute, the position of the memorial to the late Sir James Hector has been made satisfactory. Owing to the action of the Government in granting a generous subsidy, ample funds will be at the disposal of the committee for establishing a memorial that will be worthy of Sir James Hector's long and distinguished services to the cause of science in New Zealand. Observations in connection with the Arthur's Pass Tunnel were continued throughout the year. Temperature readings have been taken every ten chains and specimens collected. Early last year a committee was formed for the purpose of investigating systematically the artesian system of Christchurch and the neighbourhood. The committee has held several meetings, and has taken preliminary steps for ascertaining the extent, depth, and geological relations of the water-bearing strata, and for the examination of physical, chemical, and biological properties of the water obtained from them. Two papers by Dr. Farr and Mr. D. C. H. Florence, on the radium emanation contained in the artesian water and on the effect of the water as it comes direct from the well on trout and other fish, have already been laid before the institute.

A committee was appointed to consider the Animals' Protection Act, and to suggest amendments with the view of giving more effective protection to the native fauna of the Dominion. A conference was held with a similar committee appointed by the Canterbury Acclimatisation Society, and a number of recommendations were made which received the approval of the council. It is intended to submit the proposals to other institutes for their consideration; and if they meet with approval to bring the matter under the notice of members of Parliament and of the Minister for Internal Affairs. It is hoped later to send a party to the Chatham Islands for purposes of scientific investigation.

It is evident that the institute is not only encouraging interest in science by its monthly meetings, but is also actively engaged in promoting the progress of natural knowledge.

THE WORK OF LORD KELVIN IN TELEGRAPHY AND NAVIGATION.¹

LORD KELVIN'S work was great and many-sided. We might compare it to the cathedral in some crowded mediæval city, where no place can be found commanding a general view. You approach by one narrow street or another, seeing from each only some portion of a particular face of the building. The Kelvin lecturer has, as it were, to select his view-point, conscious that he must concentrate his attention on what is, after all, but a small part of a gigantic whole. The lecturer might, for instance, take up the mathematical work of Kelvin in the theory of electrostatics, in the theory of magnetism, in the theory of elasticity, in hydrodynamics, in the wave theory of light; his contributions to thermodynamics, which included the establishment of an absolute scale of temperature and the enunciation of the principle of the dissipation of energy; his experimental work on the electrodynamic quality of metals, his speculations on the structure of matter, his views on the age of the earth, his share in fixing the electrical units; or, on the more practical side, his electrical measuring instruments, from the electrometers of the early days to the ampere balances and wattmeters which he

designed when the need for such instruments became apparent with the growth of electrical engineering. Any one of these subjects, or others that might be named, would provide a more than ample text. To-night I have selected two portions of Lord Kelvin's work as the most suitable to bring before you, namely, his work in submarine telegraphy and in navigation. Both of these are practical matters which appeal to members of this institution. They illustrate well the bent of his genius as an engineer. In both of them he made inventions of first-rate importance—inventions which not only met an immediate requirement, but have stood the test of time; and an additional reason for the selection is the personal one that both in telegraphy and navigation it was my good fortune, as one of his young assistants, to see some of his inventions in the making.

His connection with telegraphy had begun long before, when he was only thirty years of age. It dates from 1854, and to appreciate rightly the part he began to play then I must ask you to go back as far as 1850, the year of the earliest submarine telegraph. It was in August, 1850, that a line consisting of a single copper wire, insulated by gutta-percha, wound on a great reel on the deck of a steam tug in Dover Harbour, was laid from Dover to Calais. There was no sheathing or protection of any sort; the line was what we should now call a bare core, and so light was it that lead sinkers were attached at every hundred yards to ensure its going to the bottom. In a few hours it was cut by the anchor of a fisherman, who took home a piece to show to his family as a curious new kind of seaweed; but during its brief life it gave the operators much food for thought. Accustomed only to the clear, sharp signals of land lines, they could make nothing of those got from the cable, and Mr. Willoughby Smith tells us how at each end of the line it was regretfully concluded that the operator at the other end must have been lunching, not wisely, but too well. This was the earliest experience of the effects of electrostatic induction in retarding the signals and altering their character. The cable is equivalent to an extended Leyden jar of large capacity, and at every application of the sending battery there is a gradual charging up, so that the signal current which arrives at the distant end does not at once reach its full strength; and, further, when the contact with the sending battery stops the current does not at once cease, but tails off slowly as the cable discharges the electricity it has accumulated. The current accordingly arrives in the character of a wave, slowly rising to a maximum value and then slowly subsiding each time a signal is sent.

In a short cable this causes little trouble; it only makes the process of signalling a little slower, but the instruments which serve on land lines may still be used. A successful Dover-Calais cable properly covered with a protecting sheath was laid in 1851, and was soon followed by other short lines. The general character of the electrostatic charge in a cable was explained by Faraday, and it was experimented on by Latimer Clark in a cable, 110 miles long, laid to connect England with Holland; but no one knew then in what manner the retardation of signals to which it gives rise depended on the electrical characteristics or how it would be affected in cables of different lengths or with different dimensions of core. It was in 1854 that Thomson's attention was directed to the subject by Stokes, following on a conversation at the British Association, and in this way began the connection with submarine telegraphy which was to prove of momentous import.

Thomson attacked the problem with characteristic ardour, and in less than twelve days he sent a complete solution to Stokes, which was published in fuller form in the Proceedings of the Royal Society for May, 1855. In this paper he points out that the effect of electrostatic induction is to make the flow of electricity in a cable correspond to the flow of heat in a solid conductor as investigated mathematically by Fourier. He formulates the equations and draws what is called the *curve of arrival*, the curve, namely, which shows in what manner the current gradually reaches its full value, at the distant end of the cable, when contact with the battery is made at the sending end. He shows how the current falls away when the battery is removed and the cable is put to earth; and how, in cables of different lengths but of the same

¹ From the second Kelvin lecture, delivered at the Institution of Electrical Engineers on January 13, by Prof. J. A. Ewing, C.B., F.R.S.

dimensions of core, the time taken by the current to reach any particular fraction of the full value will vary as the square of the length.

This result of the theory was of fundamental importance. It was also, at the time, of particular interest, for the project was then beginning to be mooted of connecting England and America by wire. The only experience available as to speed of signalling was on short cables, and in passing from them to a line 2000 miles long the "law of squares," as it was called, seemed at first to give little prospect that signalling across the Atlantic could be accomplished at a speed that would be commercially practicable.

To lay the cable it was coiled on board two ships of war, the British battleship *Agamemnon* and the United States frigate *Niagara*. On August 5, 1857, the shore end was landed at Valencia, and the *Niagara* began to pay out, the intention being that her section should be laid first and the *Agamemnon* should continue the work after making a splice in mid-ocean; but the paying-out gear was very crude; the brake for maintaining a proper tension in the cable was difficult to regulate, and after 300 miles were laid there was a mishap at the brake and the cable parted in 2000 fathoms. The ships returned to Devonport, the cable was stored for the winter, new machinery was designed, and some 700 miles of fresh cable were manufactured against the next attempt, to be made in the following year.

Thomson had joined the expedition at the request of his brother directors, and was on board the *Agamemnon*. He came back full of ideas as to both the electrical and the mechanical sides of the great problem. On the mechanical side he had worked out, for the first time, the theory of the forces concerned in the laying and lifting of deep-sea cables; this was published almost immediately after his return. Let me give you a brief sketch of the results of this theory.

A cable paid out from a ship going at uniform speed does not hang as a catenary, but takes the form, as it sinks, of a straight line stretching at a uniform slope from the ship's wake to the point far in the rear at which it touches the bottom. This is because each part of the cable in sinking through the water attains almost immediately a constant velocity of descent against the resistance which the water opposes to its motion. Imagine a ball, heavier than water, to be dropped from a ship. It will, after sinking a foot or two, attain a practically uniform velocity, and keep that until it reaches the bottom. Imagine, now, a ship to drop a series of such balls, at regular intervals, while she steams ahead at a steady speed. At any instant the depth through which each ball has sunk will be proportional to the time which has passed since it was dropped, and therefore to the distance run by the ship, and hence a line joining the successive balls will be a line of uniform slope. The continuous cable behaves in this respect like the row of balls, but with this important difference. Each ball sinks vertically; it has no tendency to do anything else; but the cable tends, not only to sink, but to glide along the direction of its own length, just as a rope resting on an inclined plane tends to glide down it. A certain amount of such gliding is desirable, indeed necessary, for it secures that the cable will be laid with a sufficient percentage of slack to accommodate itself to any inequalities on the bottom, and to provide for the possibility of its being raised should that be required. It is the function of the paying-out brake to apply just so much retarding force as will allow the right amount of this gliding to take place, and not too much. As cables are actually laid, there may be 10 or 12 per cent. of slack, and this means a considerable velocity of gliding motion. In a cable of the type which was afterwards successfully laid across the Atlantic, the straight line had a slope of about 1 in 8½—in other words, with a depth of two miles there were seventeen miles from the ship to the place where it touched bottom. On the gliding motion down this long slope the frictional resistance of the water is an important factor; it reduces very much the retarding force needed at the brake. If it were simply a question of holding the cable from gliding down the slope at all, the retarding force would be equal to the weight, in water, of a length of cable equal to the depth. In fact, however, it is about half that, the other half being accounted for by the fric-

tional resistance the cable experiences in gliding down the slope.

In the early summer of 1858 the cable squadron was again ready to put to sea. New paying-out brakes had been devised. Thomson had succeeded, with much difficulty, in getting systematic tests of the conductivity established during the manufacture of the additional 700 miles. Most important of all, he had invented a new signalling and testing instrument which was to make Atlantic telegraphy commercially practicable. This was the mirror galvanometer, the first description of which is found in his patent of 1858.

We have no time to linger over the story of the cable of 1858. This time the two ships, after encountering a storm of great severity, in which the coiled cable suffered severe damage, met in mid ocean, spliced the cable, and began to pay out simultaneously, the *Agamemnon* steaming towards Ireland and the *Niagara* towards Newfoundland. The cable broke when only six miles were paid out. Again the ships met to make a fresh splice, and again the cable failed when some eighty miles had run out. A third attempt promised better, for some 200 miles were laid, when again the cable broke, this time at a place where it had been injured in the storm. The ships returned to Queenstown; Bright, Thomson, and the other leaders, disappointed but not discouraged, advised the Board to order a fresh attempt. Their advice was taken. The ships once more met at the mid-ocean rendezvous, and this time success crowned their efforts. On August 5 both ships completed their task, and the ends of the cable were brought to land.

Scarcely had the enthusiasm awakened by this great event begun to subside when it was apparent that all was not well. The Irish end of the cable had been handed over to Mr. Whitehouse, who attempted with little or no success to establish communication by means of his own signalling instruments. It was only when the galvanometer of Thomson was resorted to, with a simple Daniell battery to send the current, that messages were transmitted. The Board, dissatisfied with Whitehouse's action, directed Thomson to take complete charge. Various important messages passed, but the tests showed that the insulation of the cable had broken down; a bad fault developed, which had doubtless been intensified, if not produced, by the high-tension induction coils used by Whitehouse. The signals grew more and more feeble, and in a few weeks the cable altogether ceased to speak.

It never spoke again, and not until 1865 was the attempt made to lay a new Atlantic cable. By that time much had been accomplished. It was in the intervening years that the work of establishing standards for electrical measurement was undertaken by a committee of the British Association. The committee was appointed at the instance of Thomson, and he took a prominent part in its work. Besides this, the cable engineers were busy, and were gaining experience from lines laid in other places. Methods of systematic testing were devised; a type of cable was designed which was better adapted than before to bear the strain of laying, and especially the much severer strain of picking up, and material improvements were made in the paying-out machinery.

In 1865 the *Great Eastern* was available for laying the cable. Thomson, along with Cromwell Varley, went as a consulting expert on behalf of the company. Twelve hundred miles were successfully laid, and then a fault showed itself; picking up was begun, but in manoeuvring the ship the cable parted in deep water. Attempts were made to recover it by grappling; three times it was hooked and brought part of the way to the surface, but the shackles used to couple up successive lengths of the grappling rope were too weak to stand the strain. Grapple, rope, and cable were lost, and the ship returned with the task unfinished, but with everyone now full of confidence, not only that a sound cable could be laid, but that the lost cable could be found and lifted.

In 1866 the thing was done; an entirely new cable was laid with complete success, and then the *Great Eastern* with her consorts proceeded to the lost end of the cable of 1865, and began once more to fish in water more than 2000 fathoms deep. A fortnight passed before the watchers at Valencia saw any sign; then the spot of light began

to flicker, and presently the flickerings shaped themselves into letters and words. The cable had awakened to life. A few days more and it too was complete.

Throughout the operations Thomson was in the ship; Varley remained at Valencia. Thanks to their labours, and to those of Mr. Willoughby Smith, the contractors' electrician, the appliances for testing on board ship had been brought to a degree of perfection that left nothing to be desired. By this time it was generally recognised that the credit for Atlantic telegraphy, regarded as an electrical achievement, belonged to Thomson, though in his characteristic manner he would, when speaking of the subject, dwell on the parts played by others. Along with Mr. Canning, the engineer of the expedition, and Captain Anderson, who commanded the *Great Eastern*, he received the honour of knighthood.

For a time his mirror galvanometer remained the only instrument by which conversation could be carried on. He now proceeded to design a substitute for it which should give a record of the successive electric impulses instead of merely exhibiting them to the watchful eye of a skilled clerk. To secure greater power in the movement of the indicator he inverted the function of magnet and coil, making the coil the movable piece and the magnet the fixed piece. The coil was, therefore, made very light; the magnet, which being stationary might now be very heavy, was made exceedingly strong, and was arranged so that the coil lay in an intense field between its poles. The movement of the coil actuated a very light pointer, or rather pen, in the form of a siphon-shaped tube of fine drawn glass, from which ink was deposited on a running paper band. Here we find the earliest example of the moving coil type of galvanometer, often called the D'Arsonval type by those who do not recognise its real origin. It is a type now familiar in many practical instruments for the measurement of direct-current amperes and volts; but an important element in the invention is still to be named. It was essential that the glass pen should write without friction, and Thomson effected this by the happy device of electrifying the ink so that the ink and the paper attracted one another, with the result that the siphon was maintained in a constant state of rapid vibration, alternately advancing to the paper to deposit a minute drop of ink and then springing back, but all the time free to follow, without friction, the movements of the coil in obedience to the electric impulses arriving through the cable. Dynamically the siphon recorder has to satisfy the same conditions as those that determined the design of the mirror galvanometer. It draws on the moving strip of paper a curve of arrival for every one of the successive currents of which the signals are composed.

To this day the recorder remains in universal use as the standard instrument in submarine telegraphy. It has been simplified by the substitution of permanent field magnets for electromagnets, and by the use of an electromagnetic vibrator for the siphon instead of electrification—changes which were made in later years by Thomson himself.

It is time now to turn to Lord Kelvin's work in navigation. Taking the two oldest aids to navigation, the compass and the sounding-line, he revolutionised them both. Where most men would have thought there was nothing left for invention to do he found much. He has earned profound gratitude for appliances which add immeasurably to the security of all who go to sea. He has been called the best friend the sailor ever had; and it is said that a bluejacket was once overheard to remark, "I don't know who this Thomson may be, but every sailor ought to pray for him every night."

It was about 1873 that he began to study the compass seriously, partly because he had undertaken to write an article on it for *Good Words*, and partly because he had occasion to prepare, for the Royal Society, a biographical sketch of his friend Archibald Smith, containing an account of Smith's work on the theory of the perturbation of the compass caused by the magnetism of iron ships. Kelvin's first patent for an improved compass was taken out in 1876.

He found the compass full of serious defects. For one thing it was very unsteady—that is to say, it was liable to be set swinging through a large angle when the ship

rolled. Sometimes an attempt was made to reduce this unsteadiness by introducing friction at the pivot, which, in a way, made matters worse by causing the compass to stick, pointing in a wrong direction. Under a mistaken idea of what would lead to steadiness, the card was made heavy and the needles long, and the long needles made it impossible to correct the compass properly for the magnetism of the ship. This was the most serious defect of all. In iron ships, and especially in ironclads, the compass is at the mercy of disturbing influences, which do much to mask the true directive force of the earth's magnetic field. To neutralise these is indispensable; the way to do it, as a matter of theory, had been pointed out, but it was only through the radical change in construction which we owe to Kelvin that it became possible to carry the process into effect.

He recognised that for this purpose the needles must be short. Further, that for steadiness what was wanted was a long period of horizontal oscillation—in other words, small magnetic moment relatively to the moment of inertia of the card; but, to keep the frictional error down, the weight of the card, including the needles, should be small. So he made the card as light as he could get it—a mere aluminium rim tied by silk threads to a small central boss, just as the rim of a bicycle wheel is tied to the nave by wire spokes, and from the silk-thread spokes he hung short pieces of magnetised knitting-needle to serve as the magnets. The result was that not only was the total weight very small, but it was nearly all in the rim, where it is most useful for giving moment of inertia and consequent slowness of period. Magnets and all, the card only weighs 180 grains for a 10-inch size, and yet its period of oscillation is much longer than that of the old standard compass, while its friction error is less.

Another admirable feature of Kelvin's invention was his method of keeping the compass always level and free from pendulum-like oscillation. He hung the bowl, as usual, from gimbals, but with knife-edges instead of the usual round spindles at the trunnions, and under the card he provided a chamber at the bottom of the bowl partly filled with castor-oil. You see this in the glass bowl now on the table. There is a glass partition to separate the place where the compass card stands from the lower part of the bowl, and in the lower part is the castor-oil. Its function is to damp out any oscillation of the bowl that may tend to be set up by the rolling or pitching of the ship, and it does so by dissipating the energy of such swings. At the same time the knife-edge gimbals leave the compass perfectly free to take up a true level.

Another feature is that the bowl and gimbals as a whole is hung from springs to withstand vibration caused by the action of the screw, or in warships by gun-fire.

Now as to the correction for the magnetism of the ship. Let me indicate very briefly the nature of that problem, and how it is solved.

An iron ship is a great magnet, or rather a great aggregate of many magnets. Her magnetism at any instant springs from two causes. First, there is the more or less permanent part, which she takes up first when she is built; it depends to a great extent on how her head lay while she was on the stocks. Then there is the induced part, which changes with every change of course—a transient effect due to the induction of the earth's magnetic field. Strictly speaking, the induced magnetism is not entirely transient, nor is the other by any means entirely permanent; but the ideal division into transient and permanent is a highly useful one provided we understand the limitation within which it is to be accepted. Now think of what happens when the ship is "swung," that is, turned so that she heads successively on all points. The permanent magnetism will cause an error of the compass which will be of the same nature as you would find if you placed a compass needle on a fixed pivot and disturbed it by turning a bar magnet slowly round a vertical axis. This error will reach a maximum twice in the revolution, once to one side and once to the other side—in other words, once in each semicircle. Hence it is called the semicircular error. The permanent magnetism of the ship has a vertical component, and this causes not only semicircular error, but also a heeling error, namely, a deflection of the compass when the ship inclines to either side.

By a combination of three sets of correcting magnets, two horizontal and one vertical, Kelvin obtained complete neutralisation of the disturbing effect of the ship's permanent magnetism, both as respects semicircular error in change of the ship's course, and heeling error as she heels or rolls. From time to time, if the condition of perfect compensation is to be maintained, the position of these various correctors has to be altered, because of changes which take place in the so-called permanent magnetism of the ship. The navigator has always to be on the look-out for the gradual development of errors from this cause, however perfectly the first adjustment has been carried out.

We have next to consider the effects of induced magnetism. The most important of these arise from the fact that the ship is a long body of magnetisable material turning in a horizontal plane, and therefore subject to the inductive influence of the horizontal component of the earth's magnetic field. Think of what would happen if we were to take a pivoted compass needle and place it above or below a bar of soft iron, and slowly turn the bar round in a horizontal plane. We are to think of the bar as having no appreciable magnetic hysteresis, so that in every position it is the induced effect only with which we have to do. What will be the nature of the deviation? When the bar points north, and again when it points south, there is no deflection of the needle, for though the magnetism of the bar is then at its strongest, the field due to it is in the line with the undisturbed earth field; also when the bar points east or west there is no deflection, for the bar then takes up no magnetism; but between these points, namely, when the bar is pointing N.E., S.E., S.W., or N.W., the deflection is at its maximum. So in a ship's compass this error, due to the purely transient magnetism induced by the horizontal component of the earth's field, has its maximum on these four courses, once in each quadrant, and for that reason it is called the quadrantal error.

It is due, as we have seen, to the ship's being a long body, extending fore and aft, and it is corrected by balancing this excess of fore and aft iron by other iron, placed quite near the compass and on either side of it. The two balls which you see on the side of the Kelvin binnacle are the correctors for quadrantal error. They are adjusted, in the first place, by selecting a suitable size of ball, and then placing them nearer to or further from the compass until, on swinging the ship, the quadrantal error disappears. The possibility of correcting the quadrantal error in this way had been pointed out by Airy as early as 1840; but with the old form of compass card and needles it could not be done, because of the excessive length and large magnetic moment of the needles. To apply the method to a compass of the old pattern would have needed globes of impracticable size, not a few inches in diameter as these are, but weighing tons. Kelvin, with his short needles on a light card, made it possible to carry out the process; and so gave the world, for the first time, a compass that would point truly to the magnetic north, notwithstanding all the perturbations due to permanent and induced magnetism in the iron of the ship.

One more of these disturbing causes remains to be mentioned. The vertical component of the earth's field induces magnetism as well as the horizontal component, and gives rise to an additional error of two kinds; namely, a further semicircular error and a further heeling error. These are distinct from the semicircular error and heeling error due to permanent magnetism, and the right way to correct them is to fix a bar of soft iron in a vertical position¹ near the binnacle, so that the magnetism induced on it will act as a counter-balance. This is the Flinders bar, so called because its use was pointed out by Captain Flinders as early as 1801. It has generally to be fixed in front of the binnacle, and in Kelvin's compass it is made in several separate lengths of soft iron, which can be put together to make up a bar giving any necessary amount of correcting effect.

The main function of the Flinders bar is to correct the semicircular error due to induced vertical magnetism. So far as the heeling error is concerned it also helps, but in practice it is found convenient to correct a part of the

heeling error due to induced magnetism by means of the same kind of permanent magnet correctors as I have already described in speaking of the heeling error due to permanent magnetism, namely, vertical magnet bars placed in a can in the binnacle directly under the centre of the compass card. The number and height of these bars has therefore to be altered from time to time, as the ship moves to regions where the vertical force is different. When the heeling error is fully corrected we escape one cause of the unsteadiness which a compass shows when a ship rolls, for we escape the magnetic cause of oscillation, namely, the alternate magnetic pull to port and starboard; but a purely dynamical cause of unsteadiness necessarily remains, arising from the fact that the point of suspension of a compass card must be placed some way from the centre of gravity to hold the card level against the dipping action of the earth's magnetic field. Consequently, every roll to either side applies a mechanical couple tending to set up oscillation, and if the period of the roll were the same, or nearly the same, as the period of oscillation of the card, the disturbance would become so great as to make steering by compass impossible. It was to secure steadiness in this sense that Kelvin strove to give his compass card a long period of oscillation, recognising that the right way to obtain steadiness was to make the period much longer than the period of the slowest rolling motion liable to occur in a ship, at the same time keeping the friction as small as possible. The problem of securing a steady, frictionless compass was a problem where, as in the invention of the mirror galvanometer, his genius for practical dynamics guided him to the right solution. In the case of the compass it was rendered difficult by the fact that other conditions, apparently antagonistic, had at the same time to be satisfied in order that the correction of magnetic errors might be completely carried out.

The evolution of the Kelvin compass, in its main features, took about five years; but a longer task lay before the inventor in overcoming the professional conservatism of sailors, the objections of the so-called practical man, active hostility in some quarters, and the passive resistance of official inertia. Gradually the compass came to be used in merchant vessels of the best appointed class. Enlightened navigators such as Captain Lecky, the author of the well-known "Wrinkles," became its enthusiastic advocates. Foreign admiralities took it up, and in our own service individual officers were quick to see its merits. Captain Fisher, now Admiral of the Fleet Lord Fisher, was warm in its praise after observing its behaviour in ships under his command, first in the *Northampton* in rough weather and afterwards in the *Inflexible* during the firing of heavy guns in the bombardment of Alexandria. That was in 1882; but it was not until November, 1889, that the superintendent of the Compass Department of the Admiralty was in a position to inform Lord Kelvin that his 10-inch compass was to be adopted as the standard compass for the Navy. This was twelve years after the date of his patent, and more than eleven years after he had laid the invention formally before the First Lord. The way of the inventor, like that of the transgressor, may still be hard, but I trust it is not so hard now as it was then. One does not care to dwell on the spectacle of a Kelvin spending his strength in disheartening effort as the sea beats against a cliff. It is painful to read the correspondence and discussions of these weary years. One does it with increased admiration of the infinite patience which at last secured to us the benefits of his practical genius.

The use of the Kelvin compass may now be said to be universal, except that in the Navy a modified form, due to Captain Chetwynd, with a card immersed in liquid, is taking the place of the Kelvin dry card in the newer ships as being steadier still under gun-fire. The system of correction remains substantially unchanged, and the compass continues to embody the same mechanical features as formed the basis of Kelvin's invention.

In the navigational sounding machine we have another invention of first-rate importance, second only to the compass in practical value to sailors, and remarkable for its extreme simplicity. It was his cable-laying experience that first led Kelvin to take an interest in deep-sea sounding. The process, as then carried out, was a laborious one. The line was a rope an inch and a half in circumference,

¹ That is to say, vertical when the ship is on even keel or perpendicular to the deck.

and though it carried a very heavy sinker, the resistance to its motion through the water was so great that it took a long time to reach the bottom. For the same reason the ship had to be stopped while the line ran out, and, except in shallow water, while it was being heaved in. Many hands were needed, and much time was spent in making a cast. Hence it came about that the operation of sounding, beyond the use of the hand-lead in quite shallow water, was but little resorted to as an aid to navigation, notwithstanding the importance of the indications it could give in such cases as when a ship was approaching land in a fog or in circumstances which made the exact position uncertain, when the depth might be anything up to, say, one or two hundred fathoms.

I have spoken already of Thomson's study of the forces acting on a cable during its submersion. Applying these principles to the sounding-line, he recognised that to make the line slip down quickly it should have the smallest possible and the smoothest possible surface, and this led him to use a single wire of steel—the steel of high tensile strength used in pianofortes. In 1872 he demonstrated the practicability of using wire by taking a sounding and finding bottom at 2700 fathoms in the Bay of Biscay with a 30-lb. sinker and a single wire of No. 22 gauge. He soon devised a suitable drum and winding-in wheel for deep-sea use, and from this was developed later a compact form of navigational sounding machine by which flying soundings are taken without stopping the ship.

In a flying sounding the wire streams out behind, taking an oblique course to the bottom, and the length of wire that runs out is greatly in excess of the depth. To read the depth directly, Thomson invented several forms of depth gauge, the simplest of which is a long narrow glass tube, closed at the top, and coated inside with chromate of silver or some other chemical which is discoloured by the action of sea-water. This tube is put in a protecting case, which is attached near the sinker, and as it descends the increased pressure forces the sea-water up into it, compressing the air, and indicating the depth by the height to which the chemical lining is discoloured. Accordingly, the depth is read off by laying the tube against a scale, when the line is again drawn on board.

This machine has become a standard navigational appliance. The length of wire in common use is 300 fathoms. A strand of seven fine steel wires, which gives greater flexibility, is now substituted for the single wire. It runs out under a regulated tension, supplied by a rope brake, which retards the rotation of the drum on which the wire is wound. When the sinker touches bottom the tension is at once seen to slacken, or rather felt to slacken by a sailor who keeps a little rod of wood lightly pressed against the wire while it runs out; the drum is stopped, and the wire is slowly wound in again by hand, or in the latest naval type by electric motor. Lord Kelvin's final improvements in the machine were made only a year or so before his death; they were, in fact, his last serious inventive work. They include a large horizontal dial for reading the number of fathoms of wire out, and with this it is often practicable to tell the depth very closely without resorting to a depth gauge at all; for in the modern machine the action is so uniform that, at any given speed of ship, a definite relation holds between the depth and the length of wire out, and by finding this relation once for all a table can be prepared by which the speed is known, and so when the length of wire out is observed the depth may be at once inferred. This system is now in regular use in the Navy. A pair of the Kelvin machines stand on the bridge; the wire runs out along a boom at either side and over an ingeniously designed pulley or fair-lead; whenever soundings are wanted, they can be taken systematically and in quick succession while the ship proceeds at unaltered speed, and the depth is called out for the information of the navigating officer almost as soon as the wire has stopped running out. Alike in the Navy and the merchant service, there is no difficulty in making it a matter of routine to keep the sounding machines going incessantly when near shore or within, say, a hundred fathoms in thick weather.

Dr. Ewing then went on to speak of Lord Kelvin's advocacy of the Sumner or "position-line" method of working out sights at sea, and his tables for facilitating

Sumner's method; also his harmonic analysis of the tides and his tide-predicting machine.)

In attempting this account of the work of Kelvin in telegraphy and navigation, I am embarrassed by its volume and its range. The time has proved far too short for a fitting notice of discoveries and inventions so various, so fundamental, so far-reaching in their practical effects. Yet we have dealt only with a very small part of the whole achievement of a man not less remarkable for sustained industry than for outstanding originality—a man incessant in action and in thought—of whom it may be truly said that there is no department of physics on which he has not left an abiding impress.

I have said nothing to-night of the lofty flights of scientific imagination, which are, perhaps, his highest title to fame; but I have said enough to show that Kelvin was no mere philosopher with head in the clouds. He was quick to recognise a real need, quick also to see how the need should be met. He found material for invention in the most commonplace appliances, because his mental habit was in everything to seek for the how and the why and to ask himself in what way the thing might be done better. He had an infinite faculty of taking pains, of adhering to a purpose until he secured its full accomplishment, of going on from improvement to improvement in pursuit of the more perfect result, and with all this a courage and hopefulness that no opposition could damp, that never accepted defeat.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—Dr. E. W. Hobson, F.R.S., fellow, tutor, and lecturer in mathematics at Christ's College, has been elected Sadlerian professor of pure mathematics. Dr. Hobson was senior wrangler in 1878, and has been mathematical lecturer in the University since 1884, a lecturer in Christ's College since 1879, and for the last few years Stokes lecturer. His earlier published work related principally to spherical harmonics, Bessel's functions, and other allied functions, together with the cognate subject of the theory of the potential. On these subjects he published a memoir in the Philosophical Transactions of the Royal Society, two memoirs in the Cambridge Philosophical Transactions, and a series of papers in the Proceedings of the London Mathematical Society. About the year 1900 Dr. Hobson began to publish a series of papers dealing with the theory of aggregates, that of functions of real variables, the theories of G. Cantor, and the fundamental principles of mathematical analysis; and in 1907 his treatise on the theory of functions of a real variable, and on Fourier's series, was published by the University Press. Since the appearance of this book he has, during the last two years, published several papers, in which he has given a general convergence theorem, and applied it to questions connected with the representation of functions by means of series of Sturm-Liouville functions, Legendre's and Bessel's functions, and to the elucidation and extension of the theory of Hamilton's fluctuating functions. He has also quite recently published papers dealing with Lebesgue's new theory of integration, in relation to the fundamental processes of the integral calculus.

LONDON.—The first annual report of the Military Education Committee on the work of the university contingent of the Officers' Training Corps, which was presented to the Senate on February 23, has been issued. The contingent, which was formed under the authority of a War Office letter dated January 7, 1909, numbered 24 officers and 783 enrolled cadets at the end of the year. Three units are included, an engineer unit of one company, an infantry unit of a battalion of six companies, and a medical unit of three sections of a field ambulance. An application has been submitted to the War Office for permission to organise Artillery and Army Service Corps units, and to augment the medical unit. University College has the largest number of cadets (160), King's College coming second with 132; and the medical schools, especially Guy's (67) and Middlesex (64), are well represented. The report contains much statistical information throwing light on the

ages and educational antecedents of London students. As regards the ages of cadets, the largest groups (159 and 151 respectively) fall in the age limits nineteen to twenty and twenty to twenty-one. Of the 783 cadets, 127 were educated abroad—48 in India, 48 in other British dominions and colonies, and 31 in foreign countries. The educational results achieved in the contingent appear to be satisfactory, 232 cadets having already entered for Certificate A and 3 for Certificate B granted by the War Office for military subjects. The first camp was held at Salisbury Plain in August, and the first inspection by Major-General Sir F. W. Stopford, which was held during camp, produced a highly satisfactory report.

It is announced in *Science* that a department of experimental breeding has been established in the college of agriculture of the University of Wisconsin. Dr. L. J. Cole, of the Sheffield Scientific School at Yale, has been appointed an associate professor of experimental breeding. Dr. Cole will take up his new work shortly, and will conduct investigations in the subject of experimental breeding, with special reference to the laws of heredity and improvement of animal life.

SIR GEORGE GREENHILL contributes some impressions of a visit to Berlin and its educational establishments to the *Engineer* for February 25. The chief object of his visit was to accept an invitation to examine the Militärtechnische Akademie, an establishment devoted to the instruction of officers in the science and manufacture required in modern warfare. Sir George seems to have been deeply impressed with this splendid and efficient institution, which is such as we have not in this country. Sixty officers are under instruction for a course of four years, more complete than is required now for a degree in honours at Cambridge, and their zeal and interest is said to be enthusiastic; it is considered bad form not to give the very best for the glory of the Fatherland. Of special interest was the modern ballistic laboratory established in the last four or five years; under the direction of Prof. C. Cranz. This includes lecture and experimental rooms filled with the most modern apparatus, and alongside a bomb-proof range of 60 metres. Sir George Greenhill seems to have taken delight in showing Prof. Cranz how to apply the six-point contact principle as required for a rifle rest, using for the purposes of demonstration some nails and a broomstick with broom, as a rifle was not for the moment at hand. The principle was given very clearly about 1867 in Thomson and Tait's "Natural Philosophy," but, as Sir George truly remarks, is too scientific for the official expert to grasp.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, February 24.—Sir Archibald Geikie, K.C.B., president, in the chair.—Sir William Abney: colour-blindness and the trichromatic theory of colour vision.—W. Cramer and H. Pringle: Contributions to the bio-chemistry of growth. The total nitrogen metabolism of rats bearing malignant new growths. The nitrogenous metabolism was determined in rats before and after transplantation with a rapidly growing spindle-celled sarcoma. The results show that less nitrogen is necessary to build up a certain weight of tumour tissue than is necessary to build up an equal weight of somatic tissue of the host. No evidence could be obtained that the tumour cells had a higher affinity for nutritive material than the growing cells of the host, or that they secreted substances having a toxic action on the nitrogenous metabolism of the host. The conclusion was arrived at that the cells of the new growth derived the nitrogenous material necessary for the building up of new tissue by a sparing of the protein metabolism, so that a smaller amount was utilised as a source of energy and a larger amount for the building up of new tissue.—W. Cramer and H. Pringle: Contributions to the bio-chemistry of growth. The distribution of nitrogenous substances in tumour and somatic tissues. Estimations were carried out of the total nitrogen content of rapidly growing transplanted tumours (carcinoma and sarcoma), and of the tissues of the animals

bearing these tumours. The results, which confirm those arrived at by observations on the nitrogen metabolism of tumour-bearing animals, show that the nitrogen percentage of rapidly growing tumours is smaller than that of the tissues of the host or that of the tissues of normal animals. This diminution in the nitrogen percentage was found to be due to the fact that, weight for weight, the cancerous tissue contains only about three-fourths of the amount of protein substances present in the tissues of the host. In other words, with the same amount of protein a bigger mass of tumour tissue than of host tissue can be built up. The simpler abiuret nitrogenous products of cell metabolism, however, are present in slightly greater amount in the cancerous tissue. It is pointed out that these results have a bearing on the mode of growth of cancerous tissue. Since the tissue of a neoplasm can be built up with less protein than the same weight of host tissue, the former must grow more rapidly than the latter in circumstances where both are using up nitrogenous material for mere growth at the same rate.—A. Harden and W. J. Young: The alcoholic ferment of yeast-juice. Part v., the function of phosphates in alcoholic fermentation. The two following equations were previously proposed by the authors to represent the course of alcoholic fermentation by yeast-juice:—

These were founded on (a) the determination of the amount of carbon dioxide and alcohol produced by the addition of a known amount of phosphate in presence of excess of sugar; (b) the production of a hexosephosphate of the composition $C_6H_{10}O_4(PO_4R_2)_2$; (c) the occurrence of an enzymic hydrolysis of this substance with production of free phosphate. In order to obtain further experimental justification for this view, several additional determinations have been made, and these form the subject of the present communication. The results which have been obtained are as follows:—(1) When glucose or fructose is added to yeast-juice in presence of excess of phosphate, a period of accelerated fermentation occurs, during which the added sugar undergoes the reaction (1) quoted above, one molecule of carbon dioxide being evolved for each molecule of sugar added. (2) When the available phosphate of a mixture of ferment, coferment, and sugar is greatly reduced, the total fermentation produced becomes very small. The addition of a small amount of a phosphate to such a mixture produces a relatively large increase in the total fermentation, even after allowing for the amount of carbon dioxide equivalent to the phosphate added. (3) A hexosephosphate when digested with yeast-juice is hydrolysed by an enzyme (hexosephosphatase) with production of free phosphate, and a sugar, which is capable of being fermented by yeast. As the result of this hydrolytic action the hexosephosphates when treated with yeast-juice or zymine are finally converted into carbon dioxide, alcohol, and free phosphate. In the light of these results it becomes necessary, in discussing the chemical changes which the molecule of sugar may undergo in the process of fermentation, to take into consideration the fact that two molecules of sugar are involved in the reaction.

Zoological Society, February 15.—Dr. S. F. Harmer, F.R.S., vice-president, in the chair.—R. E. Turner: Additions to our knowledge of the fossorial wasps of Australia. Many new species were described, belonging chiefly to the families Thynnidae and Ceropalidae. The Thynnidae had been collected chiefly by Mr. H. M. Giles in South-western Australia, and many interesting notes had been contributed by him on their habits. The sexual differences were extreme, and hitherto few Western Australian species had been correctly paired. The females were wingless, and the mouth-parts extremely minute, so that only liquid food could be taken, and this was usually disgorged by the male and placed in the mouth of the female. Mr. Giles had observed several cases of cross-pairing, in which the male was carrying the female of a different species; there could be no doubt as to the accuracy of this observation, though it was possible that the male claspers might be used for carrying the female when coupling did not take place. The geographical distribution

of the genus *Anthobosca* (fam. *Scoliidae*), now almost entirely confined to the Southern Hemisphere, was also discussed.—**H. H. Druce**: Descriptions of new *Lycenidae* and *Hesperiidae* from tropical South Africa. The paper contained an account of the numerous new forms collected by Mr. G. L. Bates on the Ja River, Cameroons, and by Herr Landbeck in the Upper Kasi district of the Congo.—**C. L. Boulenger**: Certain subcutaneous fat-bodies in toads of the genus *Bufo*. In *Bufo viridis*, of which the author had examined fresh material, these fat-bodies were very well developed, and on reflecting the skin from the ventral surface, one noticed a pair of gland-like fatty structures at the junction of the hind limbs with the trunk. They were present in both sexes, and varied considerably in size and colour in different individuals, but were quite constant in position.

Linnean Society, February 17.—Dr. D. H. Scott, F.R.S., president, in the chair, succeeded by Mr. H. W. Monckton, treasurer and vice-president.—**W. T. Saxton**: Recent investigations upon the anatomy of the genera *Widdringtonia*, Endl., and *Callitris*, Vent. Evidence is brought forward to show (1) that *Widdringtonia* and *Callitris* do not conform to the "Cupressineæ" type; (2) that *Widdringtonia* cannot be merged in the genus *Callitris*, but must rank as a distinct genus. *Callitrineæ* is suggested as a tribal name to include these two genera (possibly also *Actinostrobus* and *Tetraclinis*). Both morphological and anatomical differences are pointed out between *Callitris* and *Widdringtonia*, which seem more than sufficient to warrant the retention of *Widdringtonia* as a separate genus.—**G. Massee**: Evolution of parasitism in fungi. To understand clearly the evolution of parasitism it is important to grasp a fundamental point in the evolution of fungi generally. The most primitive forms were aquatic, and reproduced by zoospores, which necessitated the presence of water to secure their dispersion. As the fungi gradually took possession of dry land, a second asexual or conidia form of reproduction, suitable for dispersion by wind, &c., was gradually evolved. This supplementary conidial condition is always the form that has assumed a parasitic condition, the older sexual phase remaining as a saprophyte, and developing when the host is exhausted. Parasitism is mainly the outcome of opportunity, and the fact that fungi present all stages of parasitism, and that a saprophytic fungus can be educated to become a parasite, proves that parasitism is an acquired habit. Incipient or imperfectly evolved parasites promptly kill the host, and consequently curtail the period of their own existence, as *Pythium De Baryanum*. A higher stage of parasitism is reached by many of the rusts and smuts, *Ustilago avenae*, &c., where the host is attacked as a seedling, and is stimulated to an unusual condition of growth throughout its normal period of growth. More advanced parasites show a tendency to arrest the production of spores and conidia, and to perpetuate themselves by perennial mycelium located in some perennial vegetative portion of the host (root, tubers, &c.) or in the seed. In the most highly evolved parasites reproductive bodies are entirely arrested, and the parasite is perpetuated by hibernating mycelium only.—**T. B. Fletcher**: The *Orneodidae* and *Pterophoridae* of the Seychelles Expedition.—**Dr. G. Enderlein**: Die von Herrn Hugh Scott auf den Seychellen gesammelten *Embiidinen*, *Coniopterygiden*, und *Hemerobiiden*.—**Dr. N. F. Holmgren**: Die Termiten der Seychellen-Region.—**L. A. Borradaile**: The land and amphibious *Decapoda* of Aldabra.

Royal Anthropological Institute, February 22.—Sir Richard Martin, vice-president, in the chair.—Miss M. E. Durham: Notes on High Albania. High Albania is the only spot in Europe in which the tribal system exists intact. The tribes occupy the mountain land which forms the north-west corner of Turkey in Europe. They are exogamous, but male blood only counts. Each tribe is ruled by a council of elders, by ancient laws handed down by oral tradition, which are strictly enforced. Roughly, the tribes may be divided into three groups, one of which tells a tale of origin from Bosnia, the second of partial origin from Russia, and the third, which declares that it has "been there all the time." The tale of origin from Bosnia is confirmed by the fact that the same tattoo patterns used by these tribes are used in certain districts

of Bosnia. They consist of various arrangements of the cross, the sun, and the moon. Among other very ancient customs, the Levirate is still practised, even by many of the Roman Catholic tribes. Blood vengeance is extremely prevalent throughout both Christian and Moslem tribes. Its rules are complicated. It is undertaken rather to cleanse the honour of the slayer than to inflict punishment on the slain. Up country the houses are all stone kulas (towers), built for defence, and having no windows, but only loop-holes for rifles. Communal families of as many as forty members live together in one room, ruled by the house lord, who has often power of life and death over his subjects. Marriage is always by purchase, save for an occasional forcible capture. Children are betrothed in infancy. Thirteen to fifteen is a common age for a girl's marriage, and fifteen to eighteen for a boy. Hospitality is the universal law of the mountain. The tribesman, if he receives a traveller at all, gives him of his best.

PARIS.

Academy of Sciences, February 21.—M. Émile Picard in the chair.—**G. Humbert**: The minima of the classes of binary and positive quadratic forms.—**Armand Gautier**: The differential characters of waters arising from springs of superficial or meteoric origin and of waters of central or igneous origin. In opposition to the accepted views of Daubrée, the author regards many mineral waters as virgin springs, not arising from infiltrated water, but issuing for the first time from the earth. Somewhat similar views have been advanced by Suess. These virgin waters are characterised by their issuing from eruptive faults or in relation with metallic lodes, by being independent of the seasons and meteorological phenomena, by the constancy of their composition and temperature throughout the year, and by the presence of certain elements such as fluorine, boron, arsenic, iodine, &c., and by the absence of the carbonates of the alkaline earths.—**Gabriel Koenigs**: The conjugated curves in the most general relative movement of two solid bodies.—**H. C. Saint-Roné**: A solution of a problem of vision at a distance.—**Percival Lowell**: New canals on the planet Mars. Two large canals east of Syrtis Major were observed at the Flagstaff Observatory on September 30, and reasons are given for supposing that these canals are really new on Mars. They have the character of the other canals—a uniform line of geometrical appearance.—**Charles Nordmann**: The intrinsic brightness of the sun. The effective temperature of the solar photosphere is estimated at 6450° C. absolute. The intrinsic brightness of the sun is calculated to be 319,000 decimal candles per square centimetre.—**M. Coggia**: Observations of the comet 1910a, made at the Observatory of Marseilles with the Eichens equatorial of 26-cm. aperture. Positions are given for February 4, 5, 7, 8, 9, 10, and 11.—**W. Stekloff**: A general theorem of existence of fundamental functions corresponding to a linear differential equation of the second order.—**D. Pompéiu**: The singularities of uniform analytical functions.—**Jean Chazy**: Differential equations the general integral of which possesses an essentially mobile break.—**G. Cotty**: The transformation of Abelian functions.—**Marcel Brillouin**: Concerning functions determined by their value on a part of the boundary and that of their differential coefficient normal to the remainder of the boundary.—**A. C. Vournasos**: The reaction of nascent hydrogen in the dry state. By heating sodium formate, with or without the addition of sodium hydroxide, hydrogen is evolved. If phosphorus, sulphur, or arsenic is added to this mixture, and the whole heated to about 400° C., the corresponding hydrogen compounds of these substances are obtained. With sulphur, the pure dry sulphuretted hydrogen prepared in this way is suitable for use in analysis.—**H. Baubigny**: The separation and purification of the dithionates produced in the decomposition of silver sulphite or its double salts.—**H. Gaudechon**: The bromine derivatives of dimercurammonium.—**V. Auger**: The alkaline mangani-manganates. These compounds arise from the action of permanganates upon moist caustic soda, slowly in the cold, rapidly on warming, with loss of oxygen. The sodium salt has the composition

—**Léo Vignon**: Textiles and insoluble colouring matters.—**H. Copaux**: The inequality of the properties of the two forms (right and left) of potassium silicotungstate, and, in

general, of crystals possessing rotatory power. The salt isolated by Wyruboff was dextrorotatory only. The author has accidentally obtained a levorotatory variety, and has been able to show that these two forms differ greatly in stability, the levo variety passing over completely into the dextro form on re-crystallising from water. The two species differ considerably in their solubility.—**J. Wolff**: The action of the alkaline dibasic phosphates on tyrosinase. A reply to some remarks of M. Agulhon. Experiments are cited in detail showing that the action of the enzyme is much assisted by the presence of sodium phosphate, although at the commencement the phosphate retards the reaction.—**M. Billon-Daguerre**: The sterilisation of liquids by radiations of very short wave-length. The invisible region of the spectrum, with wave-lengths between 1030 and 1100 Angström units, is the seat of radiations possessing a chemical action about twenty-five times greater than the ultra-violet rays produced by mercury vapour lamps. The apparatus described utilises these very short radiations; details are given of its sterilising activity, and a domestic installation is figured possessing advantages economically over the mercury vapour lamp steriliser.—**Paul Hallez**: The protection encystment of *Prostoma lumbricoideum*.—**H. Vincent**: The active immunisation of man against typhoid fever. A new antityphoid vaccine.—**F. Kerfornio**: The pre-Hercynian movements of the Breton massif.—**M. de Montessus de Ballore**: The barograph considered as a recording seismoscope. Records on barographs have frequently been found to show disturbances corresponding to earthquake shocks. From the examination of four years' barograms taken at Santiago, it is concluded that the barograph cannot be regarded as a useful seismoscope.—**F. Dienert**: The estimation of fluorescent substances in the control of the sterilisation of water.

DIARY OF SOCIETIES.

THURSDAY, MARCH 3.

ROYAL SOCIETY, at 4.30.—The Depression of Freezing Point in very Dilute Aqueous Solutions: T. G. Bedford.—Sturm-Liouville Series of Normal Functions in the Theory of Integral Equations: J. Mercer.—The Solubility of Xenon, Krypton, Argon, Neon, and Helium in Water: A. von Antropoff.—Measurements of the Absolute Indices of Refraction in Strained Glass: Dr. L. N. G. Filon.

ROYAL INSTITUTION, at 3.—Illumination, Natural and Artificial (Experimentally Illustrated): Prof. S. P. Thompson, F.R.S.

Röntgen Society, at 8.15.—Dental X-ray Technique: C. A. Clark.

THE SURVIVAL OF MAN.

Survival of Man. A Study in Unrecognised Human Faculty. By Sir Oliver Lodge, F.R.S. Pp. xi+357. (London: Methuen and Co., 1909.) Price 7s. 6d. net.

THIS is a book that will attract great attention, and deservedly so. There is a well-known saying recommending men, especially judges, to give their conclusions, but never their reasons. Possibly this is wise advice in the realm of law, but it is a hopeless attitude of mind in the regions of philosophy, where the reasons are of the essence of the transaction, and the conclusions may be merely the incorrect deduction of a mind as imperfect as our own. When, therefore, a man of the standing of Sir Oliver Lodge consents, if we may use the expression, to do his thinking aloud, to lay himself open indifferently to the scoffs of the convinced unbeliever and the wistful commiseration of the unconvinced would-be believer; when he allows us to see the process by which he himself has become persuaded of the most fundamental doctrine of life, the whole community owes him a very great debt of gratitude.

To most people the question of the survival of human personality is the greatest problem of life; a positive answer one way or another would affect the actions and aspirations of mankind more than any other possible consideration or discovery. It is because of the momentous character of the subject, because of the effect that a positive assurance would have on the majority of mankind, that it has never been possible for a person who believed himself by any means to have obtained this assurance to keep the grounds of his conviction to himself. From the point of view of the present band of investigators, of which Sir Oliver Lodge is a distinguished member, having regard to the intensely intimate nature of their experiences, one may well doubt how far it has been expedient to take the general public, as yet, into the confidence of the small group of fellow-workers. Science has this great advantage over other kindred branches of intellectual activity, such as literature and art:—the general public does not profess to understand its workings; nay, a large section of the public prides itself on its inability to understand the methods of science. By this means, men of science often escape the premature notoriety which is destructive alike to patient investigation and to the inspiration of wayward genius. Especially in the case of the experiments with which Sir Oliver Lodge deals in the last chapters of his book, we may wonder how far it has been entirely discreet at present to open the discussion to the general public.

But the very magnitude of the issues at stake makes it difficult for any earnest mind to keep the results tentative as they appear, the property of a small circle. It is not easy to imagine circumstances which would justify the creation, even for a short period, of a "corner" in truth. It is therefore in accordance with the best traditions of English science that the results of these investigations, as soon as they seem to be of value to the outside world, should be at its disposal.

NO. 2106, VOL. 83]

The book before us does not profess to give an account, or even a summary, of all the work which has now been accomplished on the subjects of telepathy, clairvoyance, hypnotism, &c. As we have already said, it contains the story of the way in which, throughout the last quarter of a century, Sir Oliver Lodge has been led to believe, as the result of carefully planned experiments, if not that evidence of the survival of man—or, more correctly, of certain men—has already been collected, at any rate that there is no reason why it should not be collected. We do not think that anyone unfamiliar with the recent publications of the Society for Psychical Research will feel that he has proved his point. The nature of the evidence prevents any single or any several incidents in themselves from carrying conviction, and will always prevent it. It is the cumulative effect, added to a personal realisation of the nature of the evidence, that must be relied on. But even the proceedings of the Society for Psychical Research are published in an abbreviated form, and Sir Oliver only gives a few quotations and references to this mass of already selected facts.

At present the chief interest of the subject centres round the theory of cross correspondences, emanating chiefly from the so-called controls that are manifested in certain well-known and much discussed automatic scripts, and claim to represent the surviving personalities of Myers, Hodgson, and others. Here again the general reader cannot possibly realise how much is conveyed by the revelation of personality, in characteristic phraseology, in appropriate knowledge, in intellectual equipment. A voice in the dark may bring absolute assurance to anyone familiar with that voice of the corporal presence of a certain being, while it is meaningless or passes unheard to a person who is unfamiliar with it. Similarly, indications of known personalities, examples of typical intellectual activities continuing after earthly existence has ceased, may accumulate to such intensity that no hypothesis is so simple or so effective as that which involves the acceptance of the belief in their manifest survival; and after all, it is the essential nature of a satisfactory hypothesis, which in due course may develop into one of the so-called laws of nature, that it should offer the simplest and most effective explanation of certain ascertained facts. We do not imagine that the present book will suffice to convince anyone who is without other assurance; but we can well understand that those who have had the experience of Sir Oliver Lodge should feel that the hypothesis of the survival of man cannot long remain in the outer court of the enshrined truths of natural philosophy.

AN AMERICAN HIGH-SCHOOL BOOK ON AGRICULTURE.

Elements of Agriculture. By Prof. G. F. Warren. Pp. xxiv+434. (New York: The Macmillan Co., 1909.) Price 5s. net.

"THE purpose of the present book," says Dr. Bailey in an introductory note, "is to make the teaching of agriculture in the existing high schools comparable in extent and thoroughness with the teaching of physics, mathematics, history and literature."

C

"The interest in the teaching of agriculture," continues the author, "is but a part of a much larger question—the movement for teaching by means of things that have come within the student's experience. The underlying reason why such teaching is desirable is because it brings the schools in touch with the home life—the daily life of the community. A large part of our teaching has had no relation whatever to our daily life."

Thus the author justifies the introduction of agriculture into a high school. The subject is undeniably interesting to elder scholars whether they propose going in for farming or not, but the author goes further, and maintains that it is of real educational value and can be presented in such a way as to train the student to think. Few people would dispute these views, but we have had to wait until now for a little handbook in which they are logically carried out.

The book is not, of course, intended for elementary schools. The author presupposes some knowledge of chemistry and botany, and makes no attempt to gloss over difficulties. It is doubtful whether a scholar could study the subject profitably until he is some sixteen years of age. The author begins with the principles underlying the improvements of plants and animals by crossing and by selection. Mendel's law and its applications are dealt with at length, and mutation forms are also discussed. In illustration of the improvement effected it is shown that the percentage of sugar in the sugar beet has increased from 8 to 18 per cent. or more, whilst maize, cotton and other crops have undergone no less change. The propagation of plants forms the subject of the next chapter. Root stocks, tubers, cuttings, grafting, budding, are described in some well-illustrated pages, and then we pass to the consideration of seeds and germination tests. The student is thus led to the study of the food required by the young plant; he finds that at first it comes from the seed, afterwards from the air and the soil. A brief sketch is given of the processes going on within the plant, the manufacture of plant food, and so on. The soil is next considered; it is shown to consist of small rock particles, soil water, soil air, decaying organic matter, and living organisms, all of which are dealt with in some detail. As usual in American books great stress is laid on the importance of soil water. The reason is very obvious; two-fifths of the United States is too dry to raise good crops without irrigation, and the Government is building large reservoirs for storing irrigation water. Further, dry farming is practised there to a greater extent than anywhere else as yet. On the other hand, on the Atlantic coast the water supply is sometimes too great and a good deal of the land requires draining.

The author discusses at some length the methods for maintaining the fertility of the land. Soils have become productive by lying for ages in prairie or forest condition whilst organic matter has gradually accumulated until some sort of equilibrium is attained. With the advent of man the equilibrium is upset, the prairie is broken up, grain is grown for many years, and the wastage, which in any case would be considerable, is increased by the common

habit of burning the straw of the crops. Only in old, long-settled countries is the full value of farmyard manure appreciated. "Very few farmers in any part of America," says the author, "have yet learned to handle manure without losing one-half of its value." Among the causes of decreased productivity, erosion by wind or water is considered the worst, but it may be prevented by keeping the soil in crop as much as possible. Exhaustion of the humus supply is, however, regarded as the fundamental cause for the decrease in crop yields. Methods of restoring the fertility of the soil by means of manures, green crops, and animal excretions are described. Then follow some interesting chapters on the various crops—maize, cotton, wheat, timber and so on—their economic importance, their methods of cultivation, and the pests to which they are liable. Finally, there is a discussion on the feeding of animals.

The treatment quite justifies the author's claim that agriculture is a suitable subject for training the mind. The book is conceived in a scientific spirit, and executed with great skill. It is just the book for the young agricultural student, or, indeed, for any young student. All the illustrations are, naturally, American, but the teacher on this side will find it very useful in making up his course, although he will probably wish that an equally good book written from an English standpoint was available.

ELECTRONIC THEORY OF MATTER.

I.a Radioattività. A. Battelli, A. Occhialini, S. Chella. Pp. xxxii+xii+438. *Atti della fondazione scientifica Cagnola dalla sua istituzione in Poi.* Vol. xxii. (Milano, 1909.)

TWO of the most noticeable features of Continental publications of a scientific character are, first, the number written in a semi-scientific manner for popular consumption, and, secondly, the variety dealing with special branches of chemistry or physics in a manner capable of being readily followed by men of science interested chiefly in other branches of these subjects. The present volume is an excellent example of the second class. The first part consists of reports on essays concerned with different subjects, and is followed by the work of Prof. Battelli and his coadjutors, to whom a prize of 2500 lire and a medal were awarded for their memoir on "The Discovery of Radio-activity and its Influence on Physical and Chemical Theory."

In this book of 438 pages the chief facts of radio-activity are set forth in a most interesting and lucid style, and their bearing on chemical affinity, the electronic theory of matter, and the periodic law is discussed in a manner equally able. The standard books on conduction in gases and radio-activity usually contain too much detail, except for experts in these branches of physics; the present authors do not profess to give a full account of the facts, but only of those that are necessary to show the development of recent theory. Great praise is due, not only for the clearness with which these facts are dealt, but also for the skilful choice of material from a large mass

of detail. No book of a similar scope is published in English, and it may be recommended without hesitation to students desiring a succinct statement of facts and their bearing on modern theories of matter. Having said so much, we may perhaps be permitted to point out various small blemishes.

Chapter i. gives an account, in forty pages, of the chief results obtained by the study of gaseous conduction. The usual revolving paddle-wheel is given as an instance of the mechanical effects produced by kathode rays, but it has been shown by Stark that this is due to the heating and not to the momentum of the rays. The properties of positive rays are given in one short paragraph; as they are of outstanding interest at the present time, it might have been expected that something more recent than W. Wien's original experiments would be mentioned.

On p. 61 the extinguishing action of radium on a long spark is ascribed to the conductivity produced, but, as Peck and the present writer have shown, a far greater conductivity may be produced by Röntgen rays without producing extinction.

Chapter iii. should be especially useful to chemists, dealing as it does with the instruments used and the methods of standardising them; Wilson's tilted electroscope might have been included.

On p. 127 a method is given of demonstrating the positive charge carried by α rays; actually the indications of the electroscope would be the same if the rays were uncharged; all the experiment shows is that the β rays are charged negatively. The proper demonstration is given later.

The deduction of the transformation constants from the decay curves is exceptionally well done, as is also the question of electromagnetic mass. In connection with the latter, Sir J. J. Thomson has given reasons for thinking that the number of electrons in an atom is small; these reasons should have been mentioned in the discussion of atomic architecture.

Chapter xi. gives an account of conduction in metals according to the electronic theory. A difficulty, not mentioned here, is the fact that on this theory, according to Thomson, the energy required to raise, say, a gram of silver one degree is about ten times that shown by experiment.

Finally, in a book of such a scope we should expect to find some reference to the work of Campbell and others on the radio-activity of the commoner elements.

R. S. W.

POPULAR ASTRONOMY.

(1) *Astronomical Curiosities, Facts and Fallacies.* By J. Ellard Gore. Pp. x+370. (London: Chatto and Windus, 1909.)

(2) *Curiosities of the Sky. A Popular Presentation of the Great Riddles and Mysteries of Astronomy.* By Garrett P. Serviss. Pp. xvi+268. (New York and London: Harper and Brothers, 1909.) Price 6s. net.

IT is admittedly unwise to judge a book by its cover. It would seem to be quite unsafe to judge it by its title. Two books, by a quaint coincidence very alike in their titles, demand notice

together. Notwithstanding their initial similarity, they each appeal to a distinctly different class of readers.

(1) To anyone with an already developed interest in general astronomy the collection of "curious facts, fallacies and paradoxes" contained in Mr. Gore's book will doubtless prove interesting and suggestive. It does not pretend to tell a connected story. It certainly does not. Neither does it present a fairly complete picture of the astronomy of to-day. Elements of the subject are not dealt with, and facts loom larger than theories. It is essentially a book of "extras."

The information given, which the author believes will not be found in popular works on astronomy, has apparently been gleaned mostly, though of course not exclusively, from English and American publications of recent years. Each fact is presented in all its individuality with a local habitation and a name. It is in effect an excellent astronomical scrap-book, with the scraps arranged into chapters and with references scrupulously and copiously given.

The sun and the planets are each dealt with in sequence. The first nine pages contain statements about the sun's "stellar magnitude," temperature, possible length of life and source of heat. Remarks as to the discovery of argon and neon in the sun's chromosphere (which is probably an erroneous identification), about various observations of D_3 and concerning the discovery of sun-spots, all find a place in this first chapter. From this some rough idea of the character of the work may be gathered. Considering the great and growing importance of solar physics, this chapter might have been enlarged with profit. To allot no more space to the sun than to each of the planets in turn is surely an unbalanced treatment. The succeeding chapters devoted to comets, to double, binary and variable stars, and to nebulae, will be found closely packed with information. Following these comes a rather large section of 73 pages concerned with mythological and modern details about the constellations and their included stars. The temperament that found a dictionary the most readable of books would have gloried in these chapters. That the general reader will struggle through them it is difficult to believe.

It is not to be supposed because the work suffers from its limitations that it is not valuable. As a well-written compendium of facts it satisfies a distinct want. Where such want exists it can be recommended. The book is well printed and bound. It is fully indexed, and is light and pleasant to handle.

(2) "Curiosities of the Sky" is a book of quite another type. Here the selecting hand of the artist has been at work. "Facts" are included only when they help the presentation of the subject. The series of chapter-essays into which the publication is divided are excellently written and generally well informed. Astronomical "coal sacks," under the title of "The Windows of Absolute Night," star clusters, star streams and stellar migrations form the subject-matter of the first fifty pages. An interesting chapter on the passing of the constellations follows. Here the

author, by effective description and diagrams, shows the asterisms the Great Bear and the Hyades to be but transient phenomena, and the exquisite Corona Borealis but a passing show. New stars, nebulae, and the sun itself next provide material for the author's pen. It will be noticed that the chapters follow, in some sort, an evolutionary sequence. In spite of the temptations of the subject, extravagant and loose statements are rare, though a few have been met in reading. To state that "except for the interference of the moon, we should probably never have known that there is any more of the sun than our eyes ordinarily see" is forgetting that the spectroscope was at least a possibility whether eclipses had occurred or not. Similarly forgetful is the remark that "no instrument now in the possession of astronomers could assure us" that there are planets revolving round other stars than the sun. The statement respecting Mercury that its "average temperature is more than six and a half times that prevailing on the earth" is quite inexcusable. Some attempt at precision in a matter quite capable of being stated clearly is surely worth while.

In spite of such blemishes the book, as a popular exposition of certain phases of modern astronomy, ranks high. Hypotheses respecting the zodiacal light mystery are clearly set forth, while aurorae, comets, and meteorites are suggestively treated. Chapters dealing with the moon, Mars, and the riddle of the asteroids bring an interesting work to a conclusion. Some thirty full-page half-tone reproductions of photographs are inserted, most of them being well chosen and excellently reproduced.

The printing and binding are satisfactory, but the inset illustrations are not securely fastened and are liable to come out.

T. F. C.

WONDER BOOKS OF SCIENCE.

- (1) *The Wonder Book of Magnetism*. By Dr. E. J. Houston. Pp. x+325.
- (2) *The Wonder Book of Light*. By Dr. E. J. Houston. Pp. xii+349. (London: W. and R. Chambers, Ltd., 1909.) Price 3s. 6d. each.

DR. HOUSTON has attempted, in these two volumes, to deal with the two specified sections of physics in such a way as to render them interesting to young people. In order to attain this end he has had recourse to the somewhat novel method of frequently using fairy stories as illustrations. Dr. Houston has had considerable experience in teaching the young, and, therefore, probably knows far better than the writer the kind of treatment of the subjects most likely to appeal to them. But the general impression obtained by an adult reader is that the illustrations are, to say the least, far-fetched, and that it is surprising if children, while sufficiently young to take delight in the fairy stories, can also appreciate the serious parts of the books. We hardly expect to find in the same volume the story of "The Blowing Servant of Fortunio" and the description of Zeeman effect as "the duplication or triplication of spectrum lines when the glowing vapour is subjected to a

powerful magnetic field." Nor is it usual to associate "The Magic Wand of Prince Percinet" with a treatment of the colours of thin films and the colour of skylight.

The parts of the books which actually deal with physics are excellent. The language is generally simple, and the discussion is much more clear and exact than is usually the case in elementary treatises. Stripped of the fairy stories, both volumes could be read with much profit by grown persons desirous of enlightenment on magnetism and light. The probability is, however, that such seekers would be warned off by the juvenile complexion of the work, and thus miss the abundance of useful information contained therein. One further criticism is that some of the diagrams, of which each volume contains a considerable number, are badly reproduced. This, however, is not surprising when the low price of the books is taken into account.

With regard to the contents of the separate volumes, that on magnetism contains, besides the usual description of the properties of magnets, an interesting chapter on the history of the discovery of magnetism, and another on the possible causes of terrestrial magnetism. The auroral light and its bearing on the latter is also fully described. The reciprocal relations between magnetism and electricity are clearly stated, and a chapter is devoted to the electromagnetic theory of light. As examples of the less serious side of the volume may be mentioned the chapters entitled "Have Magnets Healing Powers?" and "Magnetism and Magic."

Among the special subjects treated in the volume on light, attention may be directed to the chapter entitled "The Light Mill," in which Crookes's radiometer is described, and to those on optical illusions and the effects of persistence of vision. Others are phosphorescence and fluorescence, X-rays and radioactivity, photography, soap-bubble colours, opalescence and polarised light. These are all dealt with quite briefly, but, nevertheless, in a lucid and interesting manner.

In conclusion, one may congratulate the juvenile readers upon having these two books so carefully written on their behalf, and express the hope that some time the author may see his way to publish the volumes in a slightly revised form suitable for older children.

OUR BOOK SHELF.

The Periodic Law. By A. E. Garrett. International Scientific Series. Pp. vi+294. (London: Kegan Paul and Co., 1909.) Price 5s.

THIS book may be viewed in two aspects—as a body of information and as a narrative. As a body of information it is very comprehensive. In no other work dealing with the periodic law, so far as the present writer knows, has the statistical information been set forth so fully and discussed in such detail. The author deserves all the credit due to a laborious compiler, and it may seem ungrateful to make any qualification in acknowledging such services. Little seems to have been omitted in the way of

facts. The more recent work on tellurium is not adequately dealt with, nor is there a reference to the calculations of Strutt in reference to Prout's hypothesis, but there is little occasion for complaint on this head and much to acknowledge. There is a good deal of historical detail as well, and on all these grounds Mr. Garrett's book will no doubt find its way to scientific libraries and be valued as a book of reference.

When, however, we come to view the book as a narrative, it suffers from its wealth of detail, and does not seem to be in line with the well-known series to which it belongs. This is perhaps a matter which concerns the editor more than the reviewer; but the periodic law can furnish a capital narrative of a type which made the International Scientific Series famous a generation ago, a type which is preserved in the recent welcome additions. From this point of view Mr. Garrett's book is not only impaired by its abundance of statistics, but by carelessness of style. The English is very far from smooth, and such sentences as "Many things, no doubt, in some measure helped to bring about the state of affairs which proved to be the natural forerunners of such a climax" are very uncomfortable to an arm-chair reader. A. S.

Leitfaden der Pflanzenkunde für höhere Lehranstalten.

By Dr. K. Smalian. Pp. 326. In five parts. (Leipzig: G. Freytag; Vienna: F. Tempsky, 1909.) Price, part i., 1 mark; part ii., 1.25 marks; part iii., 1.30 marks; part iv., 2.25 marks; part v., 2 marks.

In these days, when many authors attempt to compress as much information as possible into their textbooks, it is unusual to find an introduction to morphological and systematic botany spread over five annual courses. It should, however, be noted that each course is a short one, sufficient for one term's work, or possibly for two.

The first volume contains a series of descriptions of individual plants, arranged, according to their flowering periods, from March to July, and, so far as possible, in a sequence of complexity. A further series is given in the second course, as well as a few comparative summaries of related plants by which family limitations are introduced. The third and fourth parts are similar, except that the family synopses are more numerous, and eventually plant-associations are explained. In the fifth volume the author describes types of the Coniferæ, pteridophytes, and lower cryptogams, including the bacteria and myxomycetes; he also presents an account of the more common plants of economic value, and a brief epitome of plant geography. In addition, summaries are provided at the end of each volume, partly to recapitulate main facts, and partly for drawing comparisons. In this way the Linnean system is expounded in the third and fourth volumes. Numerous artistic coloured plates add considerably to the value of the book, especially where they depict the plants in natural habitats and associations.

The production of the book, the subject-matter, and the arrangement all merit strong commendation. The fundamental training in morphology by means of practical observation leads naturally to classification and ecology of plants. But two general objections suggest themselves; first, that there is need for more physiology, and, secondly, that in five annual courses a schoolboy could be taught considerably more botany than is contained in these volumes; as regards the latter, there is no reason why after the first summer session the remaining parts should not

be taken more expeditiously. It may also be suggested that a good account of plant distribution instead of so many cryptogamic types would have been much more suitable for the last volume.

Die Bienen Afrikas nach dem Stande unserer heutigen Kenntnisse. By Dr. H. Friese. Edited by Dr. Leonhard Schulze. Pp. 85-475, and plates. (Jena: Gustav Fischer, 1909.) Price 36 marks.

This important work is primarily based on the collections made by Dr. Schulze, who obtained forty-two species in Western South Africa as against forty-seven recorded by Bingham for the Transvaal and Natal. But Dr. Friese has taken the opportunity to include the Ethiopian region south of Senegal and Abyssinia. Abyssinia is only included in respect of *Xylocopa*, and Madagascar is excluded, as it has a separate fauna already discussed by Saussure in Grandidier's work.

A prominent feature of Prof. Friese's work is the series of maps of Africa showing the distribution of various species of bees throughout Africa; while other maps show the distribution of various important genera of African bees throughout the world. This is followed by a short bibliography, and even on the same page the technical portion of the work is commenced by a list of the thirteen African species of *Prosopis*. This is followed by a table of five South African species after Alfken and descriptions of the whole thirteen species, in the original language (Latin, German, or English) in which they were published. The remaining genera and species are similarly treated, a list of all the species being first given, and sometimes (but not always) a more or less complete table of the species, before they are described. On p. 124 an elaborate figure is given of the mouth-organs of *Polyglossa capensis*, n.sp. The book concludes with a list of thirty-five genera and 783 species of African bees (including the subspecies of *Apis mellifica*), many of which are described as new in the present volume, and an alphabetical index. The two coloured plates of bees, &c., are excellent. W. F. K.

Logic of Nature: a Synthesis of Thought. By Arthur Silva White. Pp. 58. (Privately printed by T. and A. Constable.)

This is an attempt to "outline a system of thought by which unity of world-conception may be predicated." It is a large order—vulgarily speaking—and a pamphlet of fifty-eight pages cannot be expected to give very clear notions of the author's views. Neither can a short review give a very clear notion of the pamphlet, which, for the rest, is very tough reading even for those who have spent much time and thought on the subject. The following "heads," however, will suggest the general drift.

There are four spheres or planes in the macrocosm: lithosphere, hydrosphere, atmosphere, and ethersphere, which last-named is "the psychosphere of mind"—"the energy of thought." Matter is the vehicle of energy. Intelligence is at the root of things; immanent Deity must be postulated. "*Nature is the thinking-process of the God-head*"—a striking and suggestive phrase.

The author quotes appositely from Sir J. J. Thomson, Sir J. Larmor, Snyder, and others on the physical side; and from Spinoza, Mill, Spencer, and Hamilton on the side of logic or metaphysics. His conclusion is of course idealistic. "The ultimate reality of the sum of things cannot—so far as man is concerned—have existential import except in terms of thought; and therefore thought itself is the ultimate reality" (p. 36).

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. No notice is taken of anonymous communications.]

Dr. H. J. Hansen and the Copenhagen Museum of Zoology.

ON behalf of the zoologists who have signed the accompanying letter to Dr. H. J. Hansen, of Copenhagen, I have been asked to send a copy to you with the request that you will be good enough to publish it in NATURE.

W. T. CALMAN.

1 Mount Park Crescent, Ealing, W., March 7.

March, 1910.

To Dr. H. J. HANSEN,
The University Museum of Zoology,
Copenhagen.

DEAR DR. HANSEN,

We, being some of those among the zoologists of Great Britain who know and value your zoological work, have heard with regret that there is a chance of your leaving the Museum of Zoology in Copenhagen. We hope that this is not the case; and we more especially hope and trust that you will let no circumstances turn you aside from your important zoological investigations.

The Museum of Steenstrup, of Lütken, and of Schiötte is honoured by us all; we know and honour many of the fellow-workers and successors of those great naturalists; and we consider that among so many distinguished names your own is by no means the least distinguished.

To the researches that you have carried on for many years, partly by yourself, partly together with your learned compatriot, Sørensen, we owe the best part of our knowledge of several important orders and families of Arthropods; you figure in our text-books as the leading authority on such difficult groups as the Palpigradi, the Pauropoda, the Cryptostemmatidae, the Hemimeridae, and the Choniostomatidae; and this partial list of your works is in itself a proof that you have always laboured just where there were real gaps and imperfections in the common stock of zoological knowledge.

Your Monograph on the Choniostomatidae we would refer to in particular as a masterpiece of delicate dissection and exquisite illustration; while in one and all of your publications we recognise the keenest morphological insight, and an uncommon grasp of the essential principles of classification.

With our best wishes for your prosperity, we beg you to receive from us this tribute to your powers and this testimony of our personal regard.

Very faithfully yours,

(Signed) A. Alcock, E. J. Allen, Ernest E. Austen, F. A. Bather, G. A. Boulenger, Gilbert C. Bourne, W. T. Calman, G. H. Carpenter, Wm. Eagle Clarke, C. Clifford Dobell, J. Cossar Ewart, F. W. Gamble, J. Stanley Gardiner, W. A. Herdman, Sydney J. Hickson, E. W. L. Holt, E. Ray Lankester, E. W. MacBride, W. C. McIntosh, P. Chalmers Mitchell, A. M. Norman, R. I. Pocock, Edward B. Poulton, R. F. Scharff, Adam Sedgwick, A. E. Shipley, Thomas R. R. Stebbing, J. Arthur Thomson, D'Arcy W. Thompson, Chas. O. Waterhouse.

Colour Blindness.

WHEN reading the late case of Mr. John Trattles and his colour-blindness, and when considering the discussion on the value of the tests for colour-blindness in its practical bearing for seamen and engine-drivers, it occurred to me that there was a very simple means of enabling red-blind and green-blind persons to distinguish red lights from green lights, and both of these from white lights, without their having to recognise the colours at all. I tested a colour-blind person here first with red glass and next with green glass placed in front of a cycle lamp, and he could not distinguish between the red and the green; but with the aid of my device he could distinguish the red light from the green light without fail, though he could not see them as distinct colours. The means of effecting this

is quite simple. I gave him suitable pieces of red and of green glass. I told him to look at the white light first through the red glass and then through the green glass; result, he could see the white light through either glass, though he could not distinguish the colours, but when he could see the light clearly through each separately of his pieces of glass he knew the light was not green or red, but white.

I then made the lamp shine through a piece of red glass, and told the man I was testing to look at it first through his bit of red glass and then through his bit of green glass; result, he could see the light of the lamp through his bit of red glass, but could see no light through his bit of green glass, and so he knew the light of the lamp must be red, though he did not know its colour. Next I made the light shine through a piece of green glass, and when my man looked at it through his green glass he could see the light clearly, but when he looked at it through his piece of red glass he could not see it at all, or only very, very dimly, if the green glass of the lamp was a pale green and let some white through with the green, but in either case he could say with certainty the light was green and not red or white, and this without recognising the colours as colours.

The practical application of the above facts is simple, and can be effected in a variety of manners and inexpensively. For example, a sort of double eye-glass could be made holding a suitable piece of red and of green glass and with a small handle, and made of a size easily to fit in the pocket, or, for use at sea, it might take the form of a simple night-glass with a small slider carrying the coloured glasses at the eye-piece end. Anyone can try experiments in this matter with the aid of a bicycle lamp and its green and red light on either side, and suitable pieces of red and green glass to look through.

Summary.—When the lamplight can be seen clearly through both the red glass and the green glass separately: conclusion, the light is white.

When the lamplight is seen through the red glass and not through the green glass: conclusion, the light is red.

When the lamplight is seen clearly through the green and not through the red, or only very, very dimly: conclusion, the light is green.

It is not a case of distinguishing by colour recognised, but by whether the light can or cannot be seen in each case.

I offer this suggestion in case it may be of any service, and unpatented, for the free use of all who like to use it.

Stonyhurst.

H. M.

The Meaning of Ionisation.

THE columns of NATURE are doubtless not the proper place in which to conduct correspondence classes in elementary science, but when Prof. Armstrong asks a simple question surely mere courtesy demands that he should receive a straightforward answer, such as Prof. Walker and "A. S." have not given him.

I imagine that nobody will quarrel with the following definitions:—

Ions are particles supposed to be present in some media such that, when the medium is placed in an electric field, the particles have a finite average velocity relative to the medium along the direction of the field.

"Ionisation" is used in two senses:—(1) it is used to denote the number of ions present in unit volume of the medium; (2) it is used to denote the process by which the ions are produced. Since several such processes are known, the use of the word ionisation does not connote any special hypothesis as to the mechanism by which the ions are produced.

N. R. C.

A Rare Crustacean.

YESTERDAY my assistant, Mr. G. Pyman, found several *Cheirocephalus diaphanus* swimming in a flooded ditch on Eton Wick Common. The sunlight shining on the beautiful green bodies of the males made a very striking effect. We were able to catch about twenty specimens of both sexes. I had never seen this phyllopod alive before, and, so far as I know, it has never been recorded previously from this district. The females, of brownish-purple colour, all have

full egg-cases attached to their abdomens. I put several individuals into different aquaria, and was much annoyed to find that they fell victims to various enemies during the night. A *Dytiscus* beetle, the presence of which had been forgotten, accounted for four, and four more were apparently devoured by insignificant fresh-water snails. Those, however, that were placed in a tank by themselves are alive and well, and feed on the green algæ supplied to them. The males are about $1\frac{1}{2}$ inches long, the females rather smaller.

When the river comes down in flood experience shows that it is time to be on the look-out for zoological curiosities. Perhaps *Apus* itself may reappear once more now that *Cheirocephalus* has shown the way!

Eton, March 5.

M. D. HILL.

The Formation of Large Drops of Liquid.

THE following experiment, based on the temperature-density relations between aniline and water, serves to illustrate to an audience the various shapes through which a drop passes in the course of its formation. A glass beaker, about 9 inches in height and $4\frac{1}{2}$ inches diameter, is filled to about 7 inches with distilled water, and about 80 c.c. of aniline are added. The beaker is then placed on a burner, and the temperature raised until the aniline floats to the surface of the water. On spreading out at the surface the aniline is cooled, thereby becoming denser than the water beneath. A large drop, 1 inch or more in diameter, then detaches itself from the mass at the surface, the formation being so slow that the altering shapes of the drop, the drawing out of the neck of liquid, and the thinning of the neck in two places may easily be observed. The large, detached drop falls to the bottom of the beaker, and is there re-heated, thereby again becoming lighter than the water, and rising to the surface, when a second drop is formed. By maintaining the temperature about 80° the formation of drops continues indefinitely in the manner described. The slightly pink colour assumed by the aniline enables the experiment to be seen clearly from a considerable distance, and the many beautiful shapes assumed by the drops lend an added interest to this simple method of demonstrating their formation.

The Fertilising Influence of Sunlight.

THE letters of Mr. and Mrs. Howard and of Dr. E. J. Russell in recent issues of *NATURE* point to the conclusion that the partial sterilisation of the soil improves its fertility. In connection with this subject, I would like to record that the effect of heating the soil has been observed here for some years. It has been the practice to collect all the refuse of the place that cannot be rotted, such as hedge cuttings, tree prunings, &c. These are placed on a vacant space in the kitchen garden and a fire made of them in winter. The fire is generally a large one, burning fiercely all day, and the larger branches keeping it going all night.

In the following summer the site of the fire is well marked. The rows of vegetables where they pass over it are more than a half stronger than at other parts, though they do not keep that proportion to the end of the season. The increased growth seems to be due to the heating of the soil, and not to the large amount of wood ashes left by the fire, as these are either lifted and used as a top dressing for borders where the spade cannot be used, or are spread over the vegetable ground, the site of the fire being generally left quite bare of ashes.

Ardenlea, Falkirk, March 8.

JOHN AITKEN.

MOLES AND MOLEHILLS.

LIKE that of other common animals, the complete life-story of the mole has yet to be written, exceedingly little being really known. The difficulties of observing the habits of a subterranean dweller of a most retiring disposition are patent but not altogether insuperable, and the wonder is that field naturalists have been content to read and take for granted the information handed down for the last century without any attempt to confirm it.

NO. 2106, VOL. 83]

During the winter months one cannot help noticing in the open fields here and there a mole-heap conspicuously larger than the rest. This is a male mole's winter habitation, but at present we do not know whether he lives alone or with his wife, or if the female ever constructs these "fortresses," as they are called. Probably he lives alone, and probably females make "fortresses" slightly more simple in construction and smaller in size than those of the males. If we take a spade and carefully slice away the top of a fortress, we shall find several hollow tunnels or runs, which may be opened up and followed to the base of the "fortress," whence they lead away into the field. Slicing further under these into the "fortress," and

FIG. 1.—First stage of the fortress—sectional view. R, R, Mole's run below the surface; H, H, heap of ejected earth.

just below the ground-level, we come upon a large circular cavity filled with a bundle of grass or dead leaves; this is the mole's nest in which he sleeps. If he has lately quitted it: the interior will be quite warm to the hand; the mole himself, however, will never be caught in the nest. When the nest is removed and the cavity examined, it will be found about a foot in diameter and worn smooth by the mole wriggling about as he wraps his nest round him, for that is his method of arranging himself within it. Two or more tunnels will be found leading away from the nest-cavity into the field. One of these is particularly noteworthy, as it is found in nearly every fortress;

FIG. 2.—Second stage of the fortress—sectional view. N, Nest-cavity; B, bolt-run; H, H, heap of ejected earth.

this exit leads from the bottom of the nest perpendicularly downward for about a foot, then, turning upwards, it joins another run. Its origin and use are uncertain, but it is usually regarded as a sort of sally port, and is known as the "bolt-run."

It is extremely unlikely that the mole deliberately selects the site of his fortress, as he is practically blind; probably he sets to work whenever the impulse seizes him, and proceeds in the following manner. He commences to enlarge a nest-cavity, ejecting the earth which he has loosened with his powerful claws out of a hole in the roof; this he does with the top of his head in little jerks. The quiet observer may see a sausage-shaped mass of earth issue from below

with four or five sudden jerks, then, after one or two minutes' interval, when the mole is collecting more loose earth, another sausage will appear as before, and so on until the work is complete. After the nest-cavity comes the excavation of the bolt-run, and finally, to make all safe and waterproof, the mole piles up a mass of earth, often amounting to a large barrow-load, by means of tunnels around the base of the existing heap. These tunnels sometimes break into one another and sometimes into the nest-cavity, and so cause a labyrinth which has given rise to much erroneous speculation in the past.

FIG. 3.—Sectional view of the completed fortress. T T, Tunnels formed in piling up earth from outside to make the nest-rainproof.

A fortress is often completed in a single night. The young are not born in the winter "fortress," but in a separate habitation made by the female alone. It is built on the same plan as the "fortress," but usually simpler in construction and without the bolt-run. The female produces only one litter a year, and the young, which are born from the end of April to the end of May, vary in number from two to six. Naked, blind, and pink, they turn lead-colour in ten days; after a fortnight a grey velvet pelage is visible, which becomes black at the end of three weeks, when the eyes open. The ears are opened on the seventeenth

FIG. 4.—The completed fortress viewed from above, with the tunnels T T, &c., laid bare.

day. Attempts to rear the young by hand have hitherto proved futile, for, though they will suck freely from flannel or cotton wool soaked in warm milk, they pine and die on the third or fourth day.

There has always been much discussion as to the mole's power of sight. Dissection has shown that the size of the eye is greater in the embryo than in the adult, indicating that the sight of the race has deteriorated. From numerous experiments the writer is convinced that the adult mole is practically blind. Moles encountered in the day-time have taken no notice of a human being waving a hand close in

front, nor at night do they show signs of consciousness of a light waved before their nose; but, if the slightest sound is made, the greatest excitement is instantly shown. The writer has often thrown down worms before a captive mole to test the sight. At once the mole becomes aware of the worm, but the haphazard way in which he will poke about for it with his snout shows clearly that he is guided by scent, and perhaps by hearing, but not by sight. It is true that at the least excitement the fur will radiate round the minute eye, and it has been suggested that the animal thus clears his eye to see; most probably, however, this mechanical action is retained though no longer of use, since the blind eye cannot benefit thereby. When, after a hurried and blundering search, the worm has been located, the mole holds it down with his fore paws and eats it from end to end with quick, jerky bites. When the animal's immense appetite is at length satisfied and worms are still being supplied, the mole will often give the worm several bites to disable it, and will then cram it into the earth, presumably to bury it for future use—after the manner of the dog with bones and the squirrel with acorns.

The senses of smell and hearing must be very acute to enable the mole to locate a pheasant's or partridge's nest above his run. That this is the case is testified

Photo. by

T. Bellchambers.

FIG. 5.—Young moles ready to leave the nest.

by two gamekeepers in different parts of the country, both of whom state that the nests are often entered from below and the eggs eaten.

It is surprising how soon a captive mole becomes indifferent to being handled. Within half an hour of capture it may be stroked and scratched without causing alarm; the writer has even suspended one by the tail without causing the animal to cease from lapping water. Of course, gentle handling is necessary, and avoidance of any sudden or jerky movement. Another mole soon learnt to come out of his nest and look for worms when the writer scratched the side of the packing-case in which the captive dwelt.

LIONEL E. ADAMS.

THE SOUNDS OF THE HEART.¹

THE sounds of the heart have always occupied the attention of physiologists both as regards their cause and as to their relations in time to other phenomena of the circulation, such as the impulse of the heart on the wall of the chest, and the pulse in arteries and other organs more or less distant from the heart. During the last few years much attention has been paid to these time-relations, and much

¹ Phono-Kardiogramme von Prof. Otto Weiss. (Jena: Gustav Fischer, 1909.) From Prof. E. Gaupp and Prof. W. Nagel's *Sammlung Anatomischer und Physiologischer Vorträge und Aufsätze*. Heft 7. A full bibliography will be found in Prof. Weiss's paper. Pp. 37. Price 1.50 marks.

ingenuity has been shown in devising methods by which the vibrations of those sounds, as distinct from the movements of the heart itself and the pulse in vessels, can be recorded. The older methods were subjective, and were consequently deficient in scientific accuracy. Thus, if even a skilled observer listened to the heart sounds and endeavoured to register their sequence by closing a key which acted on a recording lever, and if he endeavoured thus to register the moment of the occurrence of the first or second sound, or both, there was the inertia of the apparatus and the possibility of personal error, which made the observations of little value. It was desirable to have objective methods by which the vibrations could be actually recorded, and when one listens with the stethoscope to the strangely muffled sounds, one realises that to record the vibrations of such sounds is a remarkable achievement. At all events, the beginning and the end of the sounds can now be recorded.

Hürthle was the first to succeed in registering the vibrations of the heart sounds. This he accomplished in 1892. His method was dependent on the use of a microphone. A delicate microphone was placed on the prongs of a wooden tuning fork, and the latter was attached to the end of a large wooden stethoscope, resting on the chest wall, over the apex of the heart. The vibrations thus communicated to the microphone altered a current flowing through an electro-magnet, below which was placed a Marey's tambour (having a thin iron disc fixed to the india-rubber), and this, in its turn, transmitted its movement to a second very sensitive tambour, which recorded on a rapidly moving surface. In this way, vibrations of the heart tone were recorded, and information was obtained as to the exact moment when the tone began.

Soon afterwards, Einthoven investigated the subject by means of a microphone and capillary electrometer, and succeeded in registering with great accuracy the two tones. Then he employed his remarkably sensitive string galvanometer, and by means of this instrument, and with the aid of photography, the beginning, duration, and ending of the first and second sounds were recorded. Even in records from the impulse of the apex, which shows numerous vibrations, those associated with the heart sounds are readily identified. There can be little doubt that the string-galvanometer method is most to be depended on.

Holowinski developed a method by the construction of a kind of optical telephone. In the centre of a telephone disc, a plate of glass, like the cover-glass used in histology, was brought against a plano-convex lens, and in this way, when sounds caused the telephone plate to vibrate, the interference rings of Newton were produced. These varied with the heart tones, and, by a photographic method, when the picture of the variations was obtained, along with a superposed cardiogramme (registration of movements of apex impulse), Holowinski gave an interpretation showing the position of the tones. The picture so produced, although beautiful and interesting physically, is rather confusing.

Marbe devised a very delicate Marey's tambour, or

rather capsule, by which the vibrations of the heart-tones regulated the flow of a current of acetylene gas. This passed to a burner. The flame moved up and down with each vibration, and it was allowed to impinge on a moving band of paper. On this, with each vibration, a ring of soot was formed, and a picture of the heart tones was imprinted on the paper. The method is easy, and the results are easily interpreted.

Another method has been devised by Gerhartz. He caused a membrane (which received the sound waves) to carry, vertically to its surface, a delicate glass rod, which, at the other end, bore a small metallic mirror, placed between the poles of an electro-magnet. The arrangement is somewhat complicated, and it did not give striking results.

The last method we shall notice is that of Prof. Otto Weiss. It is entirely mechanical, and is independent of microphones and electrical appliances, being a clever modification of the phonoscope, by which, some years ago, many were amused by watching the play of colours produced in a soap film by the sounds of speech. Weiss's method consists in the employment of a soap film, in the centre of which there is attached the end of a silvered thread. The other end of the thread is fixed to a lever connected with a carrier. Vibrations are carried by a special funnel-shaped tube from the heart to the phonoscope. This is enclosed in a box having in its walls lenses

Human Heart Sounds. The upper curve is a cardiogramme of the apex beat. The lower is that of $1/100$ sec. The middle curve shows the heart sounds. Read from right to left. The first sound is the larger tracing. (Weiss.)

so adjusted that a photograph can be taken of the silvered thread and of its movements. The photograph, of course, is taken on a moving sensitive plate. The inertia of the system is remarkably small, the weight of the soap film and of the lever being about 0.000054 grm. All the parts are extremely light. The apparatus is so sensitive that the vibrations of a whisper can be recorded; the swing is aperiodic; and its moment of arrest is 0.01 sec. It is said to follow very frequent vibrations. An example of a tracing thus obtained is given in the figure.

In his interesting monograph, Prof. Weiss gives examples of tracings of cardiac sounds along with the carotid pulse, of foetal heart sounds, of the modifications of the sound caused by mitral insufficiency, mitral stenosis, aortic stenosis and insufficiency, and of anæmic sounds. All this shows the possibility of employing the method for clinical purposes. Finally, by an ingenious arrangement, Prof. Weiss has been able to reproduce the sounds by means of a telephone. A flame from a suitable lamp falls on a selenium cell in the circuit of which is a telephone. Interposed in the path of the beam of light, a disc is rotated having the curves of the heart sounds cut out on its margin. As it is rotated, the effect of the intermittent light on the selenium cell is such as to reproduce the heart tones in the telephone. Such an arrangement may be useful in teaching.

JOHN G. MCKENDRICK.

THE DAVY-FARADAY LABORATORY.

THE late Dr. Mond was keenly interested in the progress of science in all its branches, and his interest exhibited itself in a very practical manner. He was always ready to aid experimenters in carrying out costly researches, and his assistance enabled many young men to pursue original investigations of the most various kinds. Perhaps, however, the most conspicuous instance of his munificent aid to science was his founding of the Davy-Faraday laboratory. This institution was founded and maintained entirely at Dr. Mond's expense; its accommodation was placed at the disposal of investigators of all nationalities, and of both sexes, quite free of charge. It is probable that no institution of a precisely similar character is to be found elsewhere throughout the world; for it is not, in the general sense of the phrase, an educational institution: its staff comprises no one whose duty it is to give instruction, it has remained unconnected with the universities, and no sort of diploma is given to those who have worked there. It was intended to be of service to investigators, qualified by previous training to pursue original researches on their own initiative, and many such investigators have gratefully availed themselves of the facilities afforded to them.

At most institutions which foster original researches, the character of the work done is largely influenced by the professors in charge of the various departments; thus, to mention only one instance, students at the Cavendish Laboratory, Cambridge, have been engaged mostly in investigations connected with the ionisation of gases, under the inspiring influence of Sir Joseph Thomson; but at the Davy-Faraday laboratory, work of the most diverse kinds has been carried on. At the time when the present writer was privileged to occupy one of the rooms provided for investigators, researches were in progress in other rooms on such widely different subjects as the pressure produced during explosions, the rate of melting of ice under various conditions, the vapour pressure of strong solutions, the action of metals and other substances on photographic plates, the properties of platinum black, &c. It is possible that work of this character, ranging over most branches of physical and chemical science, has gained less public recognition than if a more restricted line of research had been pursued; but, for all that, the gain to science has been none the less real and lasting.

The Davy-Faraday laboratory was installed in a house adjoining the Royal Institution, Albemarle Street, and its name was chosen to honour the memory of two investigators whose labours have rendered the Royal Institution famous for ever. It was at first intended to endow the laboratory, and to place it entirely under the charge of the authorities of the Royal Institution; but, owing to some hitch in the negotiations to this end, a change of plan was decided upon: the laboratory was equipped at the expense of Dr. Mond, and a yearly grant was guaranteed for its maintenance, subject to the condition that, in the event of Dr. Mond or his heirs failing to provide this grant within a stated period of its falling due, the laboratory should become the property of the authorities of the Royal Institution.

The house in Albemarle Street was converted into a laboratory, or rather a series of laboratories, at great trouble and expense. A lift was provided for the conveyance of the workers to all floors of the building, and a well-furnished workshop was installed in the basement. In most cases workers occupy separate rooms, supplied with gas, water, and electricity; general laboratories, fitted for ordinary chemical work, can also be used. A wine-cellar was converted

into a room in which researches, demanding constancy of temperature, can be pursued. Balance rooms, and rooms for the storage of apparatus and chemicals, were provided. In short, everything was done that could possibly aid in effectively converting a dwelling-house into an up-to-date laboratory. On the other hand, rooms in a dwelling-house can hardly be rendered suitable for certain classes of investigations, however much skill and foresight may be used in their conversion; thus, delicate optical researches are rendered difficult by the shakiness of the building. But for researches in physical chemistry, for which the laboratory was especially designed, the rooms are suited admirably; and most accessories required in such researches, including some of great value, are at the disposal of the workers; in this connection, a Rowland's concave grating, and its necessary adjuncts, may be mentioned. The valuable library in the Royal Institution is placed at the disposal of workers in the laboratory.

The laboratory has been managed by a committee which included Dr. Mond, Lord Rayleigh, and Sir James Dewar as members. This committee selects the candidates who can be accommodated in the laboratory; almost from the first the working space of the laboratory has been fully utilised. The staff of the laboratory includes the superintendent, Dr. Scott, F.R.S., several assistants, and a competent mechanic. When the present writer was working at the laboratory, a delightful *bonhomie* existed between the workers; and with so many specialists on different subjects congregated under one roof, the interchange of ideas was both stimulating and instructive, and one at least of the workers profited from it, and is glad of this opportunity to acknowledge his indebtedness; he is sure that everyone who has been privileged to work in the laboratory will associate the name of Dr. Mond with feelings of lasting gratitude, stronger than it has been possible to express in these brief and inadequate reminiscences of the Davy-Faraday Laboratory.

EDWIN EDSER.

NOTES.

THE Bakerian lecture of the Royal Society will be delivered on March 17 by Prof. J. H. Poynting, F.R.S., and Dr. Guy Barlow, upon the subject of "The Pressure of Light against the Source: the Recoil from Light."

WE notice with great regret the announcement of the death, at seventy-six years of age, of Dr. E. P. Wright, for many years professor of botany in Dublin University and keeper of the herbarium, Trinity College, Dublin.

DR. H. A. MIERS, F.R.S., principal of the University of London, has been elected a member of the Athenæum Club under the provisions of the rule which empowers the annual election by the committee of nine persons "of distinguished eminence in science, literature, the arts, or for public services."

THE second annual Aero and Motor-boat Exhibition is to be held at Olympia on March 11-19, under the patronage of the King. Reviewing the list of exhibitors, it appears that the monoplane will predominate, as most of the firms are devoting their attention to this type of aircraft. In addition to the display of actual flyers, some ingenious models will be shown, while to the lover of mechanics the engines for aeronautical purposes will be of interest.

THE University of Kansas has lost its professor of mathematics by the sudden death, in his fiftieth year, of Prof. H. B. Newson. Prof. Newson was the managing editor of the University's Science Bulletin, and was the

author of numerous research articles in pure mathematics. He was a member, not only of the American Mathematical Society, but of the Deutsche Mathematike Vereinigung and the Circolo Matematico di Palermo.

THE ninth annual general meeting of the Association of Economic Biologists will be held at the University of Manchester on July 6-8, under the presidency of Prof. G. H. Carpenter. A detailed programme will be issued in due course; in the meantime, further particulars may be obtained from the honorary secretaries, Mr. W. E. Collinge, Uffington, Berkhamsted, or Mr. W. G. Freeman, 28 Burnt Ash Lane, Bromley, Kent. Mr. J. Mangan, of the University of Manchester, will act as local secretary.

FROM a Lick Observatory Bulletin we regret to learn of the death, at eighty-five years of age, of Mr. D. O. Mills, to whose generosity American astronomy—and higher education—owes very much. Mr. Mills was a member of the first board of trustees, appointed by James Lick, to superintend the construction and equipment of the Lick Observatory. To his benefactions the observatory was indebted for the two exceptionally fine spectrographs, used in connection with the great refractor, and he also provided the means necessary for the D. O. Mills expedition to the southern hemisphere, by which the observatory at Santiago, Chile, was established. His gifts to, and work for, the cause of higher education were also remarkable, both for the lavish manner in which they were freely given and the acute discernment which governed them.

THE following officers of the Pellagra Investigation Committee have been selected:—chairman, Sir T. Lauder Brunton; vice-chairman, Dr. F. M. Sandwith; honorary secretary and treasurer, Mr. J. Cantlie; advisory sub-committee, Mr. E. E. Austen, Prof. E. C. Bayly, Sir William Leishman, Dr. J. M. H. MacLeod, Sir Patrick Manson, Sir John McFadyean, Dr. F. W. Mott, and Prof. Ronald Ross. The field-workers will be Dr. Louis W. Sambon, of the London School of Tropical Medicine, and Captain J. E. Siler, with Mr. Arthur Dawson-Amoruso and Mr. G. C. C. Baldini as assistants. The standing commission for the investigation of pellagra in Bergamo has promised the inquiry every assistance.

THE eighth International Physiological Congress is to be held at the Physiological Institute of the University, Vienna, from September 27-30 next. Communications for the congress should be sent to Prof. O. v. Fürth, Physiologisches Institut, Wien IX., Wahringerstrasse 13. An exhibition of physiological apparatus is to be held from September 26 to October 1, and a special congress committee has been appointed to organise it; applications for permission to exhibit apparatus should be sent to Herrn Hofrat H. H. Meyer, Pharmakologisches Institut, Wien IX., Wahringerstrasse 13. Prof. E. B. Starling, F.R.S., of University College, London, is one of the general secretaries to the international committee, and Prof. Sigmund Exner, of the University of Vienna, is the president of the congress.

WE learn from *Science* that arrangements have been completed between Captain R. Amundsen and the Department of Terrestrial Magnetism of the Carnegie Institution of Washington regarding cooperation in magnetic work on the proposed Amundsen Polar Expedition to leave Norway this summer on Nansen's vessel, the *Fram*. After some general explorations in the South Atlantic and in the South Pacific Oceans, the *Fram* is expected to arrive in the summer of 1911 at San Francisco, where her outfit will be completed. The vessel will then be headed for Bering

Sea, and, after entering the polar basin, will drift with the ice. It is expected that it will be about four years before she emerges again from the ice. While Captain Amundsen hopes that his vessel will drift across the North Pole or close thereto, his prime object is that of general geographic exploration.

A BILL was introduced in the United States Senate on March 2 to incorporate a Rockefeller foundation in the district of Columbia. Mr. Rockefeller contemplates the endowment of an institution which will be greater even than the Carnegie foundation in educational work. The Senator who introduced the Bill said that Mr. Rockefeller had already given away 10,500,000., and is now seeking legislative means to dispose of his fortune in a way most likely to benefit mankind. The foundation, according to the Bill, is to be organised to promote the well-being and advance the civilisation of the people of the United States and its possessions, and for the acquisition and dissemination of knowledge; for the prevention and relief of suffering, and the promotion of any and all elements of human knowledge. The amount of Mr. Rockefeller's fortune is not known precisely, but five years ago it was estimated at at least 100,000,000.

THE following list of aviation meetings for the ensuing year is given by the *Deutsche Zeitschrift für Luftschiffahrt*:—March 25 to April 3, Cannes; (date not stated) Biarritz; April 10-25, Nice; April 30 to May 5, Tours; May 10-15, Bordeaux (national meeting); May 7-15, Lyon; May 10-16, Berlin (foreign competitors not dis-qualified); May 15-23, Marseille (national meeting); May 20-30, Verona; May 27-31, Limoges (national); June 5-22, Vichy (national); June 5-15, Budapest; June 5-12, Juvisy (national); June 18-24, St. Petersburg (foreigners eligible); June 10-26, Rouen; July 3-24, Rheims (French meeting); July 24 to August 4, Brussels; July 27 to August 2, Caen (national); August 6-13, England; August 6-21, eastern circuit; August 25 to September 4, Havre, Trouville; September 9-18, Bordeaux; September 24 to October 3, Milan; October 2-9, Juvisy (national); October 18 to November 2, America; December 4-18, Marseille.

A MEETING of the committee for an Arctic Zeppelin Airship Expedition was held in Hamburg on March 5 under the presidency of Prince Henry of Prussia. It was resolved to ask the Imperial Ministry of the Interior for the services of the Imperial exploration steamer *Poseidon* for ten or eleven weeks. The members of the expedition intend to start for Spitsbergen on July 1, and there to transship to the *Poseidon*. At the same time dashes are to be made into the polar ice with the hired Norwegian iceship *Phoenix* to study the conditions for airship landing. The return will be made about the end of August. The Berlin correspondent of the *Westminster Gazette* states that the original idea of making the primary object of the expedition the reaching of the North Pole has been abandoned; the main purpose is now stated to be the exploration of the unknown regions north of Franz Josef Land and Spitsbergen. Cross Bay, which has been chosen on the ground of data determined by the Prince of Monaco, will be made the base of a number of separate airship voyages which the Zeppelin airship will make. On its way north over Germany and Norway the airship will stop at stations prepared in advance.

A REUTER message from Berlin states that Germany has decided to send out an Antarctic expedition. At a meeting of the Berlin Geographical Society on March 5, Lieut. Filchner was introduced to the meeting as the leader of

the forthcoming German expedition, and briefly outlined his plan of campaign. He proposes that the main expedition shall start from a base on Weddell Sea and advance straight across the Antarctic continent to the Pole. On reaching the Pole the expedition, instead of turning back, will proceed, probably following Sir E. Shackleton's route, to the coast of Ross Sea. Meanwhile, a subsidiary expedition will have landed on the shores of Ross Sea and have advanced inland along Shackleton's route about half-way to the Pole, where, after leaving a depôt of provisions, it will turn back to the coast. The main expedition, if all goes well, will pick up the depôt of provisions and join the subsidiary party at the coast. Lieut. Filchner hopes to be able to start in October. He has already had experience as an explorer in Central Asia, where he spent the years 1903 to 1905 in exploring Tibet. He has also done exploration work in the Pamirs and Turkestan. Dr. Penck, president of the Berlin Geographical Society, announced that an anonymous donor had promised 15,000*l.* towards the expenses, and Lieut. Filchner said he had received offers of aid amounting to 3000*l.* If two ships are chartered 100,000*l.* will be required, but if one only is sent out 60,000*l.* will suffice.

THE following are among the lecture arrangements at the Royal Institution after Easter:—Dr. A. Harden, three lectures on the modern development of the problem of alcoholic fermentation; Prof. F. W. Mott, three lectures on the mechanism of the human voice; Prof. A. E. H. Love, two lectures on earth tides; Prof. C. J. Holmes, two lectures on heredity in Tudor and Stuart portraits; Dr. Tom G. Longstaff, three lectures on the Himalayan region; Mr. W. McClintock, three lectures on Blackfeet Indians in North America; Dr. W. Rosenhain, two lectures on the constitution and internal structure of alloys; Major Ronald Ross, two lectures on malaria; Mr. W. W. Starmer, three lectures on bells, carillons, and chimes; Dr. D. H. Scott, three lectures on the world of plants before the appearance of flowers; Prof. J. A. Fleming, two lectures on electric heating and pyrometry (the Tyndall lectures). The Friday evening meetings will be resumed on April 8, when a discourse will be given by Prof. P. Lowell on the Lowell Observatory photographs of the planets. Succeeding discourses will probably be given by Prof. W. J. Pope, Mr. T. Thorne Baker, Dr. Tempest Anderson, Sir Almoth E. Wright, Prof. W. H. Bragg, Sir David Gill, Captain R. F. Scott, the Right Hon. Sir Rennell Rodd, and other gentlemen.

THE director of the Meteorological Office has given notice that from April 1 forecasts of the weather prospects more than twenty-four hours ahead will be issued as opportunity is afforded. Applications have been received at the Meteorological Office from time to time for forecasts of weather several days in advance, in addition to, or instead of, the usual forecasts which refer to the twenty-four hours reckoned from the noon or midnight following the issue of the forecasts. According to the experience of the Meteorological office, the weather conditions do not usually justify a forecast detailing the changes of weather for consecutive days. There are a number of occasions in the course of the year when the distribution of pressure is typical of settled weather, and also occasions when the conditions are characteristic of continued unsettled weather. On these occasions, and on a few others when the sequence of the weather is of a recognised type, a sentence giving in general terms the outlook beyond the twenty-four hours of the definite forecast might be useful to the general public, and, as it could be justified by the statement of definite reasons for the inference, it would come within the general

rules laid down by the office with reference to the issue of forecasts. An indication of the general prospect extending beyond the twenty-four hours' limit is frequently given in the "General Inference" which precedes the forecasts for the several districts on the sheet issued to newspapers. It is expressed in more or less technical language, and the application to the several districts might only be followed by persons acquainted with the terminology used in weather study. It is proposed, therefore, when the meteorological conditions permit, to supplement the forecasts for districts by a remark on the further outlook.

THE summary of the weather issued by the Meteorological Office for the week ending March 5 shows that the conditions were still very mild over the entire country, the excess of temperature being generally from 2° to 3°. The rainfall varied considerably in different parts of the country, but was nowhere very large, whilst there was an excess of sunshine in every part of Great Britain. On nearly all parts of the coast the temperature of the sea-water was warmer than during the corresponding period last year, the difference amounting to between 6° and 7° on the east and south-east coasts of England. The summary of the weather for the winter, comprised by the thirteen weeks ending March 5, shows that the temperature was generally in excess of the average, but not to any great extent. The rainfall was everywhere above the average, the greatest excess being 4.80 inches in the north-west of England and 3.40 inches in the south-west of England. The excess was more than 2 inches in every district of the United Kingdom, except in the north and east of Scotland and in the Channel Islands; the largest actual measurement was 16.49 inches, in the west of Scotland, and the least 7.14 inches, in the east of England. The duration of bright sunshine for the winter was everywhere in excess of the average, the greatest excess being sixty-two hours in the south-east of England, and more than fifty hours in the east and north-west of England and in the Midland counties; the absolutely longest duration was 236 hours, in the south-east of England, and the least 146 hours, in the north of Scotland.

IN *Man* for February Mr. A. M. Blackman publishes some interesting notes on Egyptian antiquities and customs. Several noted tombs of Sheykhhs, with the rites performed at them, are described, such as the custom of sleeping in the sacred precincts, as was done at Greek shrines of Asklepius, and of hanging up bandages there as a charm to secure recovery from circumcision and other operations. The Copts, we are told, slay a sheep at the threshold as the bride enters the house. She must take care to cross it without staining her feet or clothes in the blood. Should this occur the marriage is deemed unlucky.

IN the *Gypsy Lore Journal* for January Mr. W. Crooke discusses the ethnographical results of the article published in vol. ii. of the journal by Mr. E. O. Winstedt on "Gypsy Forms and Ceremonies." An examination of this extensive collection of Gypsy rites and ceremonies might be expected to throw light on the supposed Indian origin of the Gypsies. The result is that, except in some not important cases, the analogy with Indian customs is not satisfactorily established. It would seem that most of the customs of the European Gypsies result from their long contact with western peoples, such as the inhabitants of Asia Minor and the Balkan Peninsula.

THE higher classes in India, particularly those who have assimilated some of the culture of the West, have been actively asserting their claims to political and social equality with Europeans. They are confronted with a

similar problem, which is likely to cause no little embarrassment. The depressed classes are now claiming similar rights from their higher brethren. The Pariahs of Madras have formed an organisation, and in Bombay the question is so serious that the Guicowar of Baroda has been moved to advocate more consideration for them. The movement has now spread to Bengal, where the Jugi weavers have issued a manifesto, prepared by Prof. Radha Govinda Nath, urging that they are really sprung from the Yogi ascetics, and are entitled to social status like that of Brahmans. They repudiate the theory generally held that they represent the decayed Buddhist communities, who on the decay of their faith were, like other depressed religionists, compelled to adopt menial occupations. It will be interesting to watch the reception which their claim receives from the Babus of Bengal.

To vol. xi. of the Proceedings of the Washington Academy of Sciences Dr. F. H. Knowlton contributes a paper to prove that the Hell Creek and Ceratops beds of Montana, which have been usually regarded as of Upper Cretaceous age, are really the equivalents in time of the Tertiary Fort Union formation. Evidence in favour of this view is stated to be afforded by the plants, invertebrates, and vertebrates of the formations in question, and the author concludes by the definite statement that the Hell Creek, Somber, and Ceratops beds are stratigraphically, structurally, and palæontologically inseparable from the Fort Union beds, and therefore of Eocene age. To this view Mr. T. W. Stanton, in the same issue, replies that, in his opinion, the Ceratops beds are of Cretaceous age on account of their stratigraphical relations, the pronounced Mesozoic character of the vertebrate fauna and its lack of Tertiary types, and the close relation of its invertebrates to those of the Cretaceous. The admitted relationship of the flora to that of the Eocene is regarded as of minor importance.

In Nos. 1 and 2 of the Research Bulletin of the State University of Oklahoma Mr. H. H. Lane describes the breeding and placentation of the nine-banded armadillo, and likewise proposes a revised classification of the Edentata. As a rule, this species produces four young at a birth, one for each of the four mammae, and from the circumstance that in the cases which came under the author's observation the young in each litter were of the same sex, and were contained in a common chorionic vesicle, it is considered probable that they were all derived from a single fertilised egg, and that the sex is determined in the latter. The placenta is of a deciduate type intermediate in form between the zonary and the discoidal, and as this type does not precisely conform to the "placenta zono-discoidalis" of Strahl, it is proposed that it should be known as "placenta zono-discoidalis indistincta." The author divides the Edentata into the Tæniodonta (extinct), Xenarthra, Pholidota, and Tubulidentata. Wortman is considered to be justified—in opposition to the view of W. B. Scott—in regarding the Tæniodonta (or Ganodontia) as represented by the Conoryctidae and Stylinodontidae, in the light of un-specialised ancestral Edentates.

Dr. Raymond Pearl and Dr. Frank M. Surface have been studying the egg-production of selected fowls with the view of answering the question, "Is there a Cumulative Effect of Selection?" and their conclusions have been published under this title in the *Zeitschrift für induktive Abstammungs- und Vererbungslehre* (Band ii., 1909, Heft 4). Two distinct experiments were made. The first, inaugurated by the director of the Maine Agricultural

Experiment Station and the late Prof. G. M. Gowell, consisted in the continued selection of fluctuating variations with the view of increasing the fecundity. The second dealt with the inheritance of fecundity. The experiments were conducted on a large scale, and yielded extremely interesting, although from the poultry farmer's point of view very disappointing, results. Systematic selection carried on for nine consecutive years yielded no increase in the average production of the flocks, nor was there any decrease in variability as regards egg-production. Egg-producing ability is apparently not inherited; on the contrary, the daughters of hens which laid 200 or more eggs *per annum* actually laid, on an average, a smaller number of eggs than the daughters of less prolific birds. These results seem to have an important bearing on the theory of natural selection.

STUDENTS of cytology who are interested in the dynamical aspects of the phenomena of karyokinesis will welcome a paper on this subject, by Prof. Angel Gallardo, in the *Archiv für Entwicklungsmechanik der Organismen* (Band xxviii., Heft 1), a separate copy of which has been sent to us by the author. Prof. Gallardo interprets the division of the cell as a bipolar phenomenon of an electro-colloidal character. He regards the cell as a complex mixture of positive and negative colloids of different potential, of electrolytes, and of neutral coagulated substances susceptible or not of induction. He considers that the chromatin carries a negative, and the cytoplasmic colloids a positive, charge. The centrosomes are supposed to be capable of acquiring a positive potential higher than that of the cytoplasm. This potential increases through unknown causes, and determines the division of the centrosome. The radiations which appear around the separating daughter-centrosomes are chains of force, formed by the orientation of cytoplasmic microsomes. The trajectories of the centrosomes during separation are the resultants of their mutual repulsion and of the attraction of the nucleus. The chromatin divides during the metaphase by repulsion of its chromosomes under a high negative potential, and the two groups of daughter-chromosomes separate under the double action of their mutual repulsion and of the attraction of the centrosomes. The two new nuclei thus formed attract the positive cytoplasm, and thus determine the division of the cell itself. The paper also contains a useful *résumé* of the views of other writers, such as Hartog and Delage, on this interesting subject.

A FEW years ago we noted with pleasure the commencement of the *Bio-chemical Journal*, and congratulated the editors, Prof. Benjamin Moore and Mr. Edward Whitley, of Liverpool, on their enterprise in starting a periodical in which bio-chemists could publish their researches. The chemical side of biological investigation is well to the fore at the present time; physiologists, pathologists, botanists, and others are devoting themselves to the unravelling of nature's secrets by chemical methods; chairs and lectureships in the subject are being established in our universities and colleges; the subject has a rapidly growing literature of its own, and journals dealing with it are published in Germany and America as well as in Liverpool. The undertaking has met with an unqualified success, and the first number of the fifth volume has just been published. The occasion is signalled by the appearance of the journal in a form more worthy of the matter it prints, both cover and the quality of the paper used being improved. The papers in it indicate the manifold way in which chemical research is invading all branches of bio-chemical study; the first, by Major Sutherland and Captain M'Cay, deals with the influence of salts on hæmolysins, with special

reference to the blood destruction which occurs in the tropical disease known as blackwater fever. This is followed by a note on a new method for determining the alkalinity of the blood, by Drs. Boycott and Chisholm. The editor and his colleagues contribute two important papers, one relating to the bearings of the physical properties of colloids and of adsorption on physiological problems, and the other to the properties of a new sapogluco-side obtained from Mowrah seeds. Papers on the action of ether on the circulation by Dr. Embley, and the influence of the pancreas on glycolysis in muscle by Dr. Simpson, bring the number to a conclusion. We have to congratulate the editors on their success in adding to British scientific literature a journal of such a high standard.

THE advantages offered to students of natural history by the opening of a "mountain" laboratory at Tolland, Colorado, situated at a considerable elevation, yet immediately accessible by train, forms the subject of an article contributed by Prof. F. Ramaley to the University of Colorado Studies (vol. vii., No. 1). Swamp meadow, grass-land, scrub, pine, and spruce forests are found in the immediate vicinity, while a short railway journey up or down gives access to Alpine conditions or vegetation of a warmer region.

A SECOND paper by Mr. E. P. Stebbing on undescribed species of Indian boring beetles of economic importance belonging to the family Scolytidae is published as the second part of the zoological series of Indian Forest Memoirs. Three species of Scolytus were taken on the deodar; in this respect they agree with the American types which infest conifers, whereas the Japanese and European species, including the well-known *Scolytus destructor* of the elm, infest dicotyledonous trees. Four species of *Tomicus* were discovered on different conifers, and a fifth was collected on the sál tree, *Shorea robusta*. Two species of *Pityogenes*, also taken on coniferous trees, are remarkable for their wide distribution.

SYSTEMATIC papers are prominent in the first part of the twenty-fourth volume of Transactions and Proceedings of the Botanical Society of Edinburgh. A short list of seaweeds collected in the West Indian island of Dominica is contributed by Mr. S. Grieve, and Mr. A. Bennett discusses the validity of *Naias flexilis* and *Atriplex calotheca* as British and Scottish species respectively. Miss I. M. Hayward prefaces a list of Tweedside alien plants with the remark that wool is largely imported into the district; this probably explains the presence of two species of *Senecio*, a *Helipterum* and *Atriplex spongiosa*, all Australian plants, and *Cenia turbinata*, a common weed throughout Cape Colony. An anatomical description of thorny aerial roots of the palm, *Acanthorhiza aculeata*, is communicated by Miss B. Chandler. They emerge as soft green roots, but on lengthening shed their root-cap, and eventually become hardened into thorny structures; they function, at any rate in the early stages, as breathing roots.

AN elaborate and extremely useful account of the Indo-Malayan woods, with a systematic enumeration of the trees furnishing them, is presented by Dr. F. W. Foxworthy in the botanical series (vol. iv., No. 4) of the *Philippine Journal of Science*. The author has found it convenient to summarise largely under types known by recognised common names. Attention is especially directed to the great importance of the timbers furnished by trees of the family Dipterocarpaceae, some of which are hardwoods, others are of soft or medium grades. "Rassak" applies to certain hardwoods yielded by species of *Vatica*

and *Cotylelobium*; "yacal" is obtained from species of *Shorea* and *Hopea*. Softer woods, used for planks and light constructive work, known as "lauan," "meranti," and "almon," are yielded by other species of *Shorea*, *Hopea*, and *Anisoptera*. The family of Leguminosae also supplies many valuable trees, to mention only the genera *Albizia*, *Intsia*, and *Pterocarpus*. Details are furnished of Philippine ebony trees and substitutes for other standard timbers, and a number of illustrations taken from transverse sections of the woods are provided.

PROF. G. MERCALLI, of the University of Naples, has recently published a valuable report on the Messina earthquake (*Atti del R. Ist. d'Incorruggimento di Napoli*, vol. vii., 1909), in which special attention is paid to the phenomena exhibited in the south of Calabria. Although there were no immediate precursors of the great shock, at least six slight tremors were felt during the previous month at Messina, Reggio, and other places within the meizoseismal area. The earthquake itself consisted of two shocks, or of two distinct phases, separated by a brief interval, the first part being the longer and the second the more violent, the whole shock lasting about forty seconds. On the map of the central area four isoseismal lines are drawn, the innermost being nearly elliptical, about 18-20 km. long from north to south, and about 10 km. wide, and agreeing closely with the curve laid down by Prof. Omori as bounding the strongly shaken area. The epicentre was evidently submarine, and its position cannot therefore be exactly determined. Prof. Mercalli, who has made a special study of the Calabrian earthquakes, states that two of the after-shocks of the great earthquake of 1783 originated in the same centre as the Messina earthquake, as well as four other shocks in the years 1509, 1599, 1780, and 1876.

THE current number of *Science Progress* contains the first part of a paper on recent hydrobiological investigations, by Mr. James Johnstone, of the Liverpool University Fisheries Laboratory. The paper deals with the results of the international explorations of the seas of north-western Europe, more particularly with those set forth in the papers of Nansen and Helland-Hansen, and examines the relation between the "Gulf Stream" (by which, it appears from the paper, is meant the Norwegian branch of the "Gulf Stream drift") and climate and crops in northern Europe. The series of curves worked out by Nansen and Helland-Hansen showing the remarkable parallelism between air temperature and sea temperature, growth of fir trees, and yield of various harvests in Norway is illustrated. In the absence of further investigation in lower latitudes in the open Atlantic it is still quite uncertain how far the sea temperature is determined by the varying proportions in which the northward moving water is derived from the equatorial currents, and the relations of cause and effect are still so obscure that it seems premature to conclude that it is "inevitable that the yield of the land-crops depends on the temperature of the sea."

A SOMEWHAT novel treatment of the hydrodynamical equations representing the general circulation of the atmosphere is given by Mr. F. R. Sharpe in the *American Journal of Mathematics*, xxxii., 1. Besides writing down, in polar coordinates, the equations of flow of matter and momentum for a viscous fluid, the author takes, in place of the ordinary adiabatic assumption, an equation representing the flow of energy, which latter is equivalent to the energy equation of the kinetic theory. Making use of the fact that the height of the atmosphere is a small fraction

of the earth's radius, an approximate solution is obtained in the first place neglecting, and in the second place taking account of, the earth's rotation. The author establishes an agreement at least of a qualitative character between the results of his theory and observed facts.

THE *Electrician* for February 11 contains a description, by Mr. P. A. Mossay, of a new arc-lamp known as the Timar-Dreger, which almost dispenses with mechanism and seems incapable of getting out of order. The two carbons are placed horizontally, the positive a few millimetres above the negative, and the arc forms and remains at the ends. To compensate for the want of symmetry of the light, a second pair of carbons is provided which point in the opposite direction to the first. Another new piece of apparatus of interest to illuminating engineers is the Lowden rotary mercury pump, described in the *Electrical Engineer* of the same date. The pump is not unlike the Gaede in general principle, and is much quicker in action than the pumps now used in evacuating incandescent lamps down to pressures at which blackening of the bulb is inappreciable.

FIVE years ago the geophysics laboratory of the Carnegie Institution of Washington commenced the task of re-determining, on the constant-volume nitrogen scale of temperature, the melting points of the metals from zinc to palladium. The work has now been completed, and the results are given by Messrs. Day and Sosman in the February number of the *American Journal of Science*. A platinum-rhodium thermometer bulb has been substituted for the one of platinum-iridium used in the earlier measurements, and the bulb has been surrounded by an atmosphere of nitrogen at about the same pressure as that in the bulb to prevent diffusion of the gas through the walls of the bulb. Greater uniformity of temperature throughout the furnace in the neighbourhood of the bulb has been secured, as the authors consider that this is the chief outstanding error in the use of the thermometer. By means of thermo-couples of platinum-platinum-rhodium standardised by comparison with the nitrogen thermometer they find the following values of the melting points, which may be compared with those of Messrs. Waider and Burgess, of the Bureau of Standards, given in these columns on February 17:—cadmium, 320.0° ; zinc, 418.2° ; antimony, 629.2° ; aluminium, 658.0° ; silver, 960.0° ; gold, 1062.4° ; copper, 1082.6° ; nickel, 1452.3° ; cobalt, 1489.8° ; palladium, 1549.2° .

THE first instalment of an article on the stability of flying machines, by Prof. Herbert Chatley, appears in *Engineering* for March 4. The author proceeds to inquire under what conditions such machines may be automatically stable; up to the present, only two types possessing this quality seem to have been discovered, viz. the automatic single-surface glider and the balanced glider. The first relies for its longitudinal stability on the variation of the centre of pressure with the angle of attack; the second relies on the variation in altitude of a balancer or tail surface. In each case a torque should come into existence which will bring the glider back to its original position. The author works out both cases mathematically, and points out for the first case that it is not only $\phi(\beta)$, the distance of the centre of gravity ahead of the centre of area of the plane expressed as a function of the angle of attack β , which decides the stability, but the rate of change of the torque M produced by a small alteration in β owing to a change in the velocity. There seems no doubt that surfaces which are concave on the under side are not stable without some balancing device. The question of oscillations is also discussed in this article.

BULLETIN No. 34, issued by the Engineering Experiment Station of the University of Illinois, contains an account of tests on a water-tube boiler having two types of tile-roof furnaces. The tests were conducted by Mr. J. M. Snodgrass, and in the first four the tubes of the lower row were completely surrounded by the tiles which formed the roof of the furnace; in the other four tests the under sides of the tubes were exposed to the action of the furnace gases, the roof tiles resting on the tops of the tubes. The last four tests show a slightly higher efficiency, more uniform fire control, and a lower temperature in the furnace, combustion chamber, and stack as compared with the first four tests. The covered tubes were shown to be superior in the matter of smokelessness. About 5 per cent. more water per pound of coal was evaporated with the exposed tubes, and the temperatures in the furnace and combustion chamber were found to be from 200° to 400° F. less with these tubes than with those wholly covered. Copies of the bulletin may be had gratis from W. F. M. Goss, University of Illinois, Urbana, Illinois.

MESSRS. MACMILLAN AND CO., LTD., have published the first part of a "Key to Hall and Stevens's School Arithmetic," prepared by Mr. L. W. Grenville. The price of this part is 4s. 6d.

THE *Amateur Photographer* of March 8 is a special issue, containing a number of fine reproductions of photographs, printed in two colours on art paper, as well as valuable notes on scientific and artistic aspects of photography. The price of this issue is only twopence, notwithstanding these special characteristics.

A POPULAR edition of the "Naturalist on the River Amazons," by the late Henry Walter Bates, F.R.S., has been published by Mr. John Murray at the price of 1s. net. We welcome the publication in cheap form of standard books of travel of this kind as being likely to interest the general reader in the work of scientific naturalists and explorers.

OUR ASTRONOMICAL COLUMN.

BRILLIANT FIREBALL OF FEBRUARY 27.—Mr. W. F. Denning writes:—"On February 27, at 6.55, a magnificent meteor was observed at various places. It fell slowly, and illuminated objects around like the bright ball of a Roman candle. The meteor is remarkable in two respects, namely, for its unusual proximity to the earth at the end of its career and for the intense green colour exhibited by its nucleus as it sailed down the sky. Several independent observers say the object apparently reached the horizon, or got within 2° or 3° of it, before it became extinct. Its height was certainly not more than twelve miles at the end of its luminous career, which occurred over a point about twenty miles west of the island of Anglesey. Possibly, indeed, the meteor may have fallen in the Irish Channel, but evidence must be awaited from places nearer the scene of the event than any we now possess.

"The radiant point seems to have been in the N. region of Cancer, and this is a place from which several large fireballs have been directed in past years at the end of February and early in March.

"There is good reason to suppose that the meteor penetrated our air strata so far as to arrive in a compact form and still luminous to within seven or eight miles of the earth's surface, but more exact observations can alone enable trustworthy figures to be deduced."

COMET 1910A.—Further light is thrown on the time and circumstances of the discovery of comet 1910A by Mr. Innes in a communication published in No. 4389 of the *Astronomische Nachrichten*, p. 338.

The earliest date on which the comet appears to have been seen in South Africa was January 12, when, at 14h. 25m. (G.M.T.), some workmen at the Transvaal Premier Diamond Mine saw it. They described it as an ordinary star with a tail to it, apparently a little to the right of the point where the sun rises. Apparently Mr. Innes was nearly as unfortunate as some London astronomers, for, having made a series of observations on the morning of January 17, he and his colleagues were prevented, by overcast skies, from seeing the comet again.

A number of observations now recorded in the same journal and in the *Comptes rendus* show that the comet's brightness decreased very rapidly after January 30, and this probably accounts for the disappointment of a large number of people in not seeing it after reading the accounts of its extraordinary brilliancy and beauty. M. Coggia found that on February 11 it was but a bright nebula about equally visible with a star of magnitude 8.4; on February 4 it was as faint as magnitude 7.6, and only showed faint traces of a tail near the nucleus.

HALLEY'S COMET.—An interesting popular address delivered before the Jersey Society in London by Mr. W. B. Brodrick in December (1909) is now published in *Science Progress* (No. 15, p. 492). The address contains a discussion of the historical events which have coincided with the comet's known apparitions, especially that of 1066, and some interesting quotations from early writers are given.

It is now improbable that the comet will be seen again until the third week in April, when, until its transit on May 18, it will rise shortly before the sun almost due east.

THE SUN-SPOTS OF SEPTEMBER 25, 1909.—An interesting description of the sun-spots of September 25, illustrated by photographs taken with the Rumford spectroheliograph at the Yerkes Observatory, is given by Dr. Slocum in No. 1, vol. xxxi., of the *Astrophysical Journal* (January, p. 26). The history of the spot, shown to be connected with the magnetic storm of September 25, is given from its appearance on September 1 to November 19, when it was last seen, and the Yerkes observations confirm those made at South Kensington in showing that the spot was especially active at the time of the magnetic storm. On September 24 the high-level calcium flocculi showed a spiral form over the spot, but on September 25 this had disappeared, and was replaced by a number of bridges crossing the spot. On September 27 the arrangement of these bridges had changed completely, and there was again a trace of the spiral structure. A prominence plate taken on September 30, at 3h. 48m. G.M.T., showed that the spot area was still active, for there were several prominences at the region of the limb where the spot had disappeared; a second plate, taken at 4h. 57m. G.M.T., showed that in the interval a violent eruption had occurred, and in place of a small single prominence there was a brilliant one extending some 5° or 6° along the limb, and rising, in several arches, to a height of 32,000 km.

DISPLACEMENT OF LINES AT THE SUN'S LIMB.—In publishing his important results on the spectroscopic determination of the sun's period of rotation, Dr. Halm, in 1907, directed attention to several cases where there were small displacements, of certain lines, independent of those due to rotation. Since then the matter has been under investigation at Mount Wilson, and Mr. W. S. Adams now publishes, and discusses at length, the results obtained. Too many points of interest are raised in his paper to be discussed adequately here, but one or two of the chief ones may be briefly referred to.

A great deal of the work has been carried out with the 30-foot spectrograph, used in connection with the tower telescope, thus providing photographs of large dispersion.

Seven classes of lines were selected for special discussion, so that any differential effects might be the better investigated, and altogether 470 lines were dealt with; the intensities at limb and centre, the displacement, and various remarks are tabulated for each line. Two values for the displacement are given, one the observed value, the other the value obtained after applying to this a correction of 0.002 Å. indicated by the cyanogen bands as being

probably due to motion in the line of sight produced by convection currents in the values for the centre.

These results show that the lines of titanium, vanadium, and scandium are less displaced than those of iron and nickel, and this is considered to be an indication that the cause producing the relative "shifts" is most effective at the lower levels. Lines most strengthened at the limb generally show the smaller displacements, and the explanation offered is that the intensification is a temperature effect, the higher level lines being cooler; the smaller displacement is thus in accordance with the previous conclusion.

The enhanced lines are well marked in the results, and generally show a much greater displacement than the arc lines. This is especially prominent in the case of lines extremely weak in, or absent from, the arc spectrum, as shown by the special study of eighteen lines given in Lockyer's list of the enhanced lines of iron; the line at λ 4385.548 gives a larger displacement (+0.013 Å.) than any other line on the more refrangible side of λ 5500. The suggested explanation of this peculiarity of enhanced lines is that, in the solar spectrum, they are due almost exclusively to the "granulations" on the disc. If, as has been suggested, these granulations signify masses of ascending, heated vapours, the measures at the centre would be affected by the resulting differential motion in the line of sight, and so increased displacements would result; an upward motion of 0.12 km. per sec. in the granulations would account for the results found.

Finally, the results indicate that the relative displacements are caused by pressure, although this is a general result to which there are exceptions, which further investigations may adequately explain. The action of magnetic fields, of anomalous dispersion, and various other causes are referred to, but more evidence is necessary ere their definite relation can be inferred.

THE "ANUARIO" OF THE MADRID OBSERVATORY, 1910.—From the Madrid Observatory we have received a copy of their "Anuario" for 1910, a useful volume containing the usual astronomical tables and some interesting articles on astronomical subjects. There is also a *résumé* of the solar observations made at the observatory during 1908, containing a complete daily, and summarised, record of the prominence observations, and a similar *résumé* of the meteorological observations.

THE ORGANISATION OF INDUSTRIAL RESEARCH.

AN address delivered by Mr. W. R. Whitney at the twentieth anniversary of Clark University, and reprinted from the *Journal of the American Chemical Society* in two recent numbers of the *Chemical News*, contains many suggestive and valuable passages, expressed with characteristic forcefulness. As the author is himself at the head of a staff of eighty investigators, he is well qualified to speak on the "Organisation of Industrial Research." In his view the fundamental problem is to secure men who are endowed with the essential qualities of optimistic activity and knowledge; the former he regards as of supreme importance, in view of the fact that general laws usually indicate the impossibility of a process rather than the specific conditions under which success may be achieved. Fortunately this quality can be imparted, as has been proved again and again, by the establishment of "schools" of research, many of which have become world-wide in their operation; fortunately, also, it is possible by suitable organisation to utilise the labours of those who are not so endowed to promote the achievement of the ideals conceived by the few who are; and in such an organisation it is urged that the output should be not merely proportional to the number employed, but to some higher exponential function. In such a complex scheme it is not thought to be possible to reward each investigator by royalty or by any such direct payment for his success in making discoveries of definite commercial value, on one hand because his success is only in part due to his own efforts, and on the other hand because each investigator must be freely available for carrying on lines of work in which success of this kind is not likely to ensue.

In regard to material equipment, the author holds views of a very advanced character. Necessity is not the mother of invention; knowledge and experiment are its parents. This is clearly seen in the case of many industrial discoveries; high-speed cutting tools were not a necessity which preceded, but an application which followed, the discovery of the properties of tungsten-chromium-iron alloys; so, too, the use of titanium in arc lamps and of vanadium in steel were sequels to the industrial preparation of these metals, and not discoveries made by sheer force of necessity. Much the same consideration applies to the equipment of an industrial laboratory, where the most useful tools were often acquired with no idea of the uses to which they would ultimately be put. "No good tool lives long for a single use alone. Many times we have questioned the advisability of installing some new apparatus—a vacuum furnace, a pair of metal rolls, some special galvanometer, some microscope, a hydraulic press, a power hammer, a steam digester, &c. Never, after it became a part of the equipment, has it seemed possible to proceed without it. In the single case of the electric vacuum furnace, for example, our laboratory has made almost continual use of from three to eight for the past five years. The laboratory, piped several years ago with high vacuum and with electrolytic hydrogen, besides steam, air, water, and gas, will probably never operate without them."

Similar considerations apply to a library. A library containing ten of the leading research journals of the world may be said to have in each volume about 100,000 brain-power hours, and it would be folly not to utilise a charged storage-battery of this immense capacity when it can so readily be installed.

SOME RECENT APPLICATIONS OF OZONE.

ALTHOUGH ozone has now been definitely known for nearly seventy years, its commercial production and exploitation is one of the many bye-products that have resulted from the modern development of electrical engineering. The "Ozonair" Company, of 96 Victoria Street, Westminster, has taken advantage of these developments to produce a series of compact and (in many cases) portable ozonisers which can be connected directly to the ordinary lighting circuits and set in operation by means of a couple of tumbler switches, one controlling a fan or blower, and the other a coil or transformer for energising the aluminium gauze in contact with which the ozone is produced. The simplicity of these arrangements should prove an important factor in securing the general utilisation of ozone in all those cases in which its usefulness has been conclusively demonstrated.

Most of the new designs are intended for the purification of air, and in the case of large buildings their utility and efficiency can scarcely be doubted. In a small room or in close proximity to a generator, the presence of an excess of ozone might well be disagreeable, as those who have worked with it have good reason to know, but in a crowded hall the atmosphere of a public meeting would stand to gain enormously by the freshening and purifying effects of one or two well-placed ozonisers. In cases such as the above it is difficult, and in many buildings impossible, during the winter to introduce enough air from outside to prevent the atmosphere from becoming "stuffy," but the most dangerous and unpleasant effects might well be got rid of by means of ozone.

This general idea has been worked out into a definite and novel scheme of ventilation, which is acquiring considerable popularity in Russia, where warmth and freshness have usually presented themselves as alternatives rather than as compatible qualities, and in the tropics, where the introduction of large volumes of air from the outside is sufficient to destroy whatever remnants of coolness may be retained by the use of verandahs and other devices for excluding the glare of the sun. In each of these widely differing circumstances the method used is to withdraw air from the room, purify it by screening, washing, and ozonising, cool or warm as the case may be, and return it to the room with a sufficient admixture of outside air to keep the proportion of carbon dioxide within reasonable limits. In this way a great economy of

heating or cooling is achieved, whilst the wholesomeness of the atmosphere is fully maintained.

The sterilisation of air by means of ozone has found a widespread application in brewing, where it replaces with great advantage the cumbrous and only partially effective systems of air-filtration that have been employed to protect the wort during fermentation, cooling, refrigerating, and bottling; it is also of service in protecting the yeast from contamination whilst it is being drained off from the wort.

An application of ozone of a more familiar type is in the bleaching of palm-oil for soap-making. This has usually been effected by means of bichromate and muriatic acid at a cost which may amount to as much as 30s. per ton. The bleaching of the oil by ozone is very effective, even in the case of specially bad samples, and costs little more than a tenth of this sum; in addition, the dark sediment that is thrown out during purification is much smaller in bulk, and the waste of oil is therefore greatly reduced.

It is claimed that the ozonised air produced by the new types of apparatus is entirely free from oxides of nitrogen, a point of considerable importance in many of its commercial applications.

AMERICAN ECONOMIC ENTOMOLOGY.

ACCORDING to the twenty-fifth report of the State Entomologist on the noxious and beneficial insects of Illinois, the scope of the work of the Entomological Department of that State has been very largely increased as the result of special legislative enactments, and the present report is the first to be drawn up under the new conditions. Its contents consist of three articles, one on experiments to check the corn-root aphid, a second on the habits of the corn-field ant (*Lasius niger americanus*), and a third on the insects infesting clover and alfalfa. Since all three have been already issued as Bulletins of the Agricultural Experiment Station of Illinois University, they need not be further noticed.

The mites of the group Oribatoidea form the subject of an article in vol. vii. of the Bulletin of the Illinois State Laboratory of Natural History. These mites, which are not much larger than the head of an average pin, are characterised by their hard, chitinous integument, on account of which they are commonly spoken of as beetle-mites, although they are not to be confounded with the mites infesting coprophagous beetles. They are generally found under decaying timber, beneath bark, under stones, in moss or grass, or on the twigs of trees, and do not appear to inflict any special damage on crops. In the present article Mr. H. E. Ewing describes a number of new species.

In article 2 of vol. viii. of the same publication Mr. J. D. Hood gives descriptions of new generic and specific types of thrips of the group Thysanoptera from Illinois.

Army-worms and cut-worms infesting sugar-cane in the Hawaiian Islands form the subject of Bulletin No. 7 of the Entomological Division of the Experiment Station of the Hawaiian Sugar-planters' Association, published at Honolulu. Of the various species of "army-worms," the widely spread *Cirphis unipuncta* is abundant in the islands, but the larvæ do not seem to assemble in the hordes which have given rise to the name of the group. They inflict, however, considerable damage on young sugar-cane, although, fortunately, there is an interval between the disappearance of one brood and the development of a second, which affords time for the plants to recuperate. The numbers of the grass army-worm—the caterpillars of the moth *Spodoptera mauritia*, a species indigenous to Mauritius, western Africa, and the Oriental and Australasian regions—have been kept in check in Hawaii, where they formerly did much damage, by the introduction of myna birds from India.

Since weevils are a group with which the economic entomologist has many dealings, reference may be made here to a paper on North American Curculionidae, by Mr. W. D. Price, published as No. 1708 of the Proceedings of the U.S. National Museum. A number of new species are named and described.

COLOURS OF SEA AND SKY.¹

A RECENT voyage round Africa recalled my attention to interesting problems connected with the colour of the sea. They are not always easy of solution in consequence of the circumstance that there are several possible sources of colour the action of which would be much in the same direction. We must bear in mind that the absorption, or proper, colour of water cannot manifest itself unless the light traverse a sufficient thickness before reaching the eye. In the ocean the depth is, of course, adequate to develop the colour, but if the water is clear there is often nothing to send the light back to the observer. In these circumstances the proper colour cannot be seen. The much admired dark blue of the deep sea has nothing to do with the colour of water, but is simply the blue of the sky seen by reflection. When the heavens are overcast the water looks grey and leaden; and even when the clouding is partial, the sea appears grey under the clouds, though elsewhere it may show colour. It is remarkable that a fact so easy of observation is unknown to many even of those who have written from a scientific point of view. One circumstance which may raise doubts is that the blue of the deep sea often looks purer and fuller than that of the sky. I think the explanation is that we are apt to make comparison with that part of the sky which lies near the horizon, whereas the best blue comes from near the zenith. In fact, when the water is smooth and the angle of observation such as to reflect the low sky, the apparent blue of the water is much deteriorated. In these circumstances a rippling due to wind greatly enhances the colour by reflecting light from higher up. Seen from the deck of a steamer, those parts of the waves which slope towards the observer show the best colour for a like reason.

The real colour of ocean water may often be seen when there are breakers. Light, perhaps directly from the sun, may then traverse the crest of the waves and afterwards reach the observer. In my experience such light shows decidedly green. Again, over the screw of the ship a good deal of air is entangled and carried down, thus providing the necessary reflection from under the surface. Here also the colour is green.

The only places where I have seen the sea look blue in a manner not explicable by reflection of the sky were Aden and Suez. Although the sky was not absolutely overcast, it seemed that part, at any rate, of the copious if not very deep blue was to be attributed to the water. This requires, not only that the proper colour of the water should here be blue, but also the presence of suspended matter capable of returning the light, unless, indeed, the sea-bottom itself could serve the purpose.

The famous grotto at Capri gives an unusually good opportunity of seeing the true colour of the water. Doubtless a great part of the effect is due to the eye being shielded from external glare, and so better capable of appreciating the comparatively feeble light which has traversed considerable thicknesses of water. The question was successfully discussed many years ago by Melloni, who remarks that the beauty of the colour varies a good deal with the weather. The light which can penetrate comes from the sky, and not directly from the sun. When the day is clear the blueness of the sky cooperates with the blueness of the water.

That light reflected from the surface of a liquid does not exhibit the absorption colour is exemplified by brown peaty water such as is often met with in Scotland. The sky seen by reflection is as blue as if the water were pure; but an attempt to illustrate this fact by experiment upon quite a small scale was not at first successful. A large white photographic dish containing dark-brown oxidised "pyro" was exposed upon the lawn during a fine day. Although the reflected light certainly came from the clear sky, the colour did not appear pronounced, partly in consequence of the glare of the sunshine from the edges of the dish. The substitution of a dish of glass effected an improvement; but it was only when the eye was protected from extraneous light by the hands, or more perfectly by the interposition of a pasteboard tube held close up, that the blue of the reflected light manifested its proper purity.

It would seem that the explanation is to be sought in diffusion of light within the lens of the eye, in consequence of which, especially in elderly persons, the whole field is liable to be suffused with any strong light finding access.

As regards the proper colour of pure water, an early opinion is that of Davy, who, in his "Salmonia," pronounces in favour of blue, basing his conclusion upon observations of snow and glacier streams. The latter, indeed, are often turbid, but deposit the ground-up rock which they contain when opportunity offers, as in the Lake of Geneva. A like conclusion was later put forward by Bunsen on the basis of laboratory observations. The most elaborate experiments are those of Spring, who, in a series of papers published during many years, discusses the difficult questions involved. He tried columns of great length—up to 26 metres; but even when the distance traversed was only 4 or 5 metres; he finds the colour a fine blue only to be compared with the purest sky-blue as seen from a great elevation; but when the tubes contain ordinary water, even ordinary distilled water, the colour is green or yellow-green, and not blue.

The conversion of the original blue into green is, of course, explicable if there be the slightest contamination with colouring-matter of a yellow character—i.e. strongly absorbent of blue light. Spring shows that this is the effect of minute traces—down to one ten-millionth part—of iron in the ferric state or of humus. The greenness of many natural waters is thus easily understood. Another question examined by Spring is not without bearing upon our present subject, viz. the presence of suspended matter. I am the better able to appreciate the work of Spring, that many years ago I tried a variety of methods, including distillation *in vacuo*, in order to obtain water in the condition which Tyndall described as "optically empty," but I met with no success. Spring has shown that the desired result may be obtained by the formation within the body of the liquid of a gelatinous precipitate of alumina or oxide of iron, by which the fine particles of suspended matter are ultimately carried down.

Perhaps the most telling observations upon the colour of water are those of Count Aufsess, who measured the actual transmission of light belonging to various parts of the spectrum. The principal absorption is in the red and yellow. In the case of the purest water, there was practically no absorption above the line F, and a high degree of transparency in this region was attained even by some natural waters. That these waters should show blue, when in sufficient thickness, is a necessary consequence.

In my own experiments, made before I was acquainted with the work of Aufsess, the light traversed two glass tubes of an aggregate length of about 4 metres (12 feet). On occasion the light was reflected back so as to traverse this length twice over. I must confess that I have never seen a blue answering to Spring's description when the original light was white. For final tests I was always careful to employ the light of a completely overcast day, which was reflected into the tubes by a small mirror. The colour, after transmission, showed itself very sensitive to the character of the original source. The palest clear sky of an English winter's day gave a greatly enhanced blue, while, on the other hand, isolated clouds are usually yellowish, and influence the result in the opposite direction. I should myself describe the best colour of the transmitted light on standard days as a greenish-blue, but there is some variation in the use of words, and, perhaps, in vision. Some of my friends, but not the majority, spoke of blue simply, but all were agreed that the blueness of a good sky was not approached. The waters tried have been very various. Sea-water from outside the grotto of Capri, from Suez, and from near the Seven Stones Lightship, off the Cornish coast, I owe to the kindness of friends. Of these, the two former showed a greenish-blue, the latter a full, or, perhaps, rather yellow-green, and these colours were not appreciably modified after the water had stood in the tubes for weeks. It is important to remember that the hue may, to some extent, depend upon thickness. It is quite probable that in a greatly increased thickness the Capri and Suez waters would assume a more decided blue colour; but I do not think the Seven Stones water could so behave, the colour, with 12 feet, seeming to involve the absorption of blue light.

¹ Discourse delivered at the Royal Institution on Friday, February 25, by the Right Hon. Lord Rayleigh, O.M., F.R.S.

Further observations on greater depths of sea-water would be desirable. A naval son informs me that off the coast of Greece a plate lying in 6 fathoms of water looked decidedly blue, although the sky was a dirty grey. I have doubts whether this would be generally the case in the Mediterranean; the green due to moderate thicknesses seems too decided.

Of natural fresh waters that I have tried, none was better than that from a spring in my own garden. This water is hard, but bright and clear, and it shows a greenish-blue, barely distinguishable from that of the Capri and Suez water. Distillation does not improve the blue. Neither did other treatments do any good, such, for example, as partial precipitation of the lime with alkali, or passage of ozone with the idea of oxidising humus. Wishing to try water of high chemical purity, I obtained—through the kind offices of Sir J. Dewar—water twice distilled from alkaline permanganate, and condensed in contact with silver, but the colour was no bluer. In the light of this evidence I can hardly avoid the conclusion that the blueness of water in lengths of 4 metres has been exaggerated, especially by Spring, although I have no reason to doubt that a fully developed blue may be obtained at much greater thicknesses. I should suppose that sufficient care has not been taken to start with white light. It may be recalled that overcast days are not so common in some parts of the world as in England.

A third possible cause of apparent blueness of the sea must also be mentioned. If a liquid is not absolutely clear, but contains in suspension very minute particles, it will disperse light of a blue character. Although, undoubtedly, this cause must operate to some extent, I have seen no reason to think that it is important; but the existence of three possible causes of blueness complicates the interpretation of the phenomena. Hitherto observers have not been sufficiently upon their guard to distinguish blueness having its origin in the sky from blueness fairly attributable to the water itself.

As regards the light from the sky, the theory which attributes it to dispersal from small particles, many of which are smaller than the wave-length of light, is now pretty generally accepted. To a first approximation, at any rate, both the polarisation and the colour of the light are easily explained. According to the simplest theory, the polarisation should be absolute and a maximum at 90° from the sun, and the colour should be modified from that of the sun according to the factor λ^{-4} ; but it is easy to see that there must be complications, even if all the particles are small and spherical. The light illuminating them is not merely the direct light of the sun, but also light diffused from the sky and from the earth's surface. On these grounds alone the polarisation must be expected to be incomplete even at 90° , and the certain presence of particles not small in comparison with the wave-length is another cause operating in the same direction. It is rather remarkable that, as I noticed in 1871, the two polarised components show much the same colour. The observation is best made with a double-image prism mounted near one end of a pasteboard tube, through which a suitable rectangular aperture at the other end is seen double, but with the two images in close juxtaposition. When this is directed to a part of the sky 90° from the sun, and the tube turned until one image is at its darkest, the two polarised components are exhibited side by side in a manner favourable for comparison of colours. The addition at the eye end of a Nicol capable of rotation independently of the tube gives the means of equalising the brightnesses without altering the colours. This observation, made independently by Spring, is regarded by him as an objection to the theory, and as showing that the cause of the blueness and of the polarisation is not the same. The argument would have more weight if the colours of the two components were exactly the same and in all circumstances, but I do not think that this is the case. Observations on the purer sky, to be seen from great elevations, would be of interest. The question is to what causes the second component is principally due. So far as it depends upon sky illumination, it would be bluer than the first component. Any "residual blue" of the kind described by Tyndall, and due to particles somewhat too big for the simple theory, would make a contribution in the same

direction. On the other hand, large particles under the direct light of the sun, and perhaps small ones, so far as illuminated by light from the earth, would contribute a whiter light. In this way an approximate compensation may occur, but the matter is certainly worthy of further attention.

In this connection it should be noticed that, according to the now generally received electromagnetic theory, complete polarisation at 90° requires that the dispersing particles should behave as if spherical, even although infinitely small. If the shape be elongated, there would be incomplete polarisation combined with similarity of colour even under the simplest conditions.

When the particles are no longer very small in comparison with the wave-length, the direction of maximum polarisation was found by Tyndall to become oblique, and the deviation is in the opposite direction to that which would have been anticipated from the Brewsterian law for the reflection of light from surfaces of finite area. As I showed in 1881, the gradual precipitation of sulphur from a very weak and acid solution of "hypo" exhibits the phenomena remarkably well. At a certain stage, depending on the colour of the light, the direction of maximum polarisation becomes oblique. Even when the obliquity is well established for blue light, red light still continues to follow the simpler law, and the comparison gives curious information concerning the rate of growth of the particles.

The preferential scattering of light of short wave-length involves, of course, a gradual yellowing and ultimate reddening of the light transmitted. The formation in this way of sunset colours is well illustrated by the acid hypo.

That Spring rejects this theory in favour of one which would attribute sky-blue to absorption by oxygen or ozone has been already alluded to. Although one must not conclude too hastily from the behaviour of these bodies when liquefied, it is, of course, possible that their absorbing qualities may influence atmospheric phenomena in some degree; but to attribute the blue of the sky to them seems out of the question. It is sufficient to remark that the setting sun turns red, and not blue.

An interesting question remains behind. To what kind of small particles—dispersing short waves in preference—is the heavenly azure due? That small particles of saline or other solid matter, including organic germs, play a part cannot be doubted, and to them may be attributed much of the bluish haze by which the moderately distant landscape is often suffused; but it seems certain that the very molecules of air themselves are competent to scatter a blue light not very greatly inferior to that which we actually receive. Theory allows a connection to be established between the transparency of air for light of various wave-lengths, and its known refractivity in combination with Avogadro's constant, expressing the number of molecules per cubic centimetre in gas under standard atmospheric conditions. The first estimate of transparency was founded upon Maxwell's value of this constant, viz. 1.9×10^{19} . Recent researches have shown that this number must be raised to 2.76×10^{19} , and that the result is probably accurate to within a few per cent.¹ It has been pointed out by Dr. Schuster that the introduction of the raised number into the formula almost exactly accounts for the degree of atmospheric transparency observed at high elevations in the United States, apparently justifying to the full the inference that the normal blue of the sky is due to molecular scattering; but, although there is no reason to anticipate that this general conclusion will be upset, it should not be overlooked that a molecule, especially a diatomic molecule, can hardly be supposed to behave as if it were the dielectric sphere of theory. Questions are here suggested for the decision of which the time is perhaps not yet ripe.

P.S.—The question of the colour of the Mediterranean and other waters was long ago discussed by Mr. J. Aitken—an excellent observer—in *Proc. Roy. Soc. Edin.*, 1881-2. His principal conclusions are very similar to my own. Mr. Aitken rightly insists upon the influence of the colour of the suspended matter to which the return of the light

¹ It is a curious instance of divergence in scientific opinion that while some still deny the existence of molecules, others have successfully counted them.

is due. Only when this is white has the proper colour of the water a full chance of manifesting itself. From the heights of Capri I noticed that the shallow water near the shore showed decidedly green, an effect attributed to the yellowness of the underlying sand.

A GEOLOGIC FORECAST OF THE FUTURE OPPORTUNITIES OF OUR RACE.¹

THE established custom of occasions of this kind leads the association to expect that its retiring president will address it upon some theme connected with the field of his own work. I shall not altogether ignore this custom, but I have chosen a theme that is at once peculiarly humanistic and distinctly prophetic. Geology has not usually been regarded as in any special sense a humanistic science, much less a prophetic one. But it is just because it has not been so regarded, and because I have fondly dreamed that it might become tributary in an eminent degree to humanistic problems and to a prophetic insight, that I have chosen the theme assigned for the evening.

Ever since the race came to a virile state of intelligence, it has tried to peer into the future that it might guide itself by its foresight. Now and then it has prolonged its vision beyond mere temporary concerns, and has endeavoured to prophesy the end of the race and the destruction of the earth. At all stages the depth of its vision into the things before has been close akin to the length of its vision backward and to the depth of its insight into the things about it. The lamp of the past and the illumination of the present have been its light for the future. This must doubtless always be its true method, for only as the race sees far into the past, sees widely and deeply into the present, has it any firm basis for a confident prophecy of the future. Even in its early days, the race did not fail to note that—though this may not be so of the ultimate entities—the existing forms come into existence, live their day, and pass away; why not, therefore, the race and the earth on which it dwells? Even as the race grows into its fuller maturity and the horizon of its vision is enlarged, there will doubtless still remain the conviction that there has been a beginning of the current order of things, and a like conviction that there will be an end. The enlargement of vision will only serve to bring into view an additional multitude of organisms and organisations that have come into form, endured for a time, and passed away. Any future change in human forecasts is not likely to be one of method, but one of measure. Some of the features that have entered into former prophecies will no doubt disappear, and perhaps new ones be added. The forecasts of pre-scientific times often made the doom of the earth hinge on some lapse in the conduct of man—made a physical disaster serve as a moral punishment. With a better knowledge of the moral law and of man's place in nature, this anthropic view will no doubt give place to a more consistent insight into the sequences of the moral and the physical worlds.

In the earlier days of the race the backward look was short, and the putative origin of the race and of the earth was placed but a few thousand years in the past; in consonance with this, the forward look placed the end not far in the future. So, too, as the beginning was made chaotic, the end was made cataclysmic.

The dawn of the earth sciences was followed by a new forecast, and as these sciences grew this underwent revisions and recasts. It was learned that the history of the earth stretches back not merely for thousands but for millions and tens of millions of years; that the on-goings of the earth are actuated by energies too broad and deep and strong to be swerved in their course or brought to an end by the acts of those who dwell upon it; that the march of earth-history has a mighty tread not to be measured by the merits or lapses of even our favoured race.

The trend of prophetic thought in the last century invites a closer review. The basis of forecast lay fundamentally in the mode of origin assigned the earth and in the general trend of its past history, especially the trend of those

agencies that controlled the conditions of life on its surface. The solar system was thought to have had its origin in a gaseous or quasi-gaseous nebula. The earth, as a member of the solar system, partook of this origin, and was conceived to have been, at an early stage, itself a fiery, gaseous globe. It is not needful here to review the special hypotheses or pay honour to their great authors from Kant and Laplace to Lockyer and Darwin, for the sole feature that potentially shaped the history of the earth was the early gaseous-molten state in which they essentially concurred. An alternative was, indeed, offered in the suggestion that the earth might have grown up by the accretion of small bodies, but it was then held by students of dynamics that such an origin was inconsistent with the symmetry of the system and the rotations of the planets, and so an origin in the gaseous or quasi-gaseous form was almost universally accepted, as by compulsion. Later, the gaseous earth, by cooling and condensing, was thought to pass into a molten sphere wrapped in a hot, vaporous atmosphere. This atmosphere was vast because the conditions required it to contain all the water of the globe and all the volatile matters that have since entered into the waters and the body of the earth. At a later stage a crust was logically made to form over the molten sphere, and the waters to condense upon it, swaddling the entire globe, perhaps, in a universal ocean. By further cooling, shrinkage, and deformation, the waters were thought to be drawn into basins, the land to appear, and the history of the stratigraphic record to begin. It is important to note that the main agency in this hypothetical history was loss of heat; and so, with consistent logic, loss of heat was made to lie at the bottom of the great events of the earth's subsequent history, and, in the forecast, to be the chief cause of its doom. From a plethora of heat, of air, and of ocean, putative loss followed loss in the past, and by prophecy loss is to follow loss in the future until emaciation, drought, and fridity mark the final state and the end of all life.

As the body of the earth cooled and shrank and permitted penetration, the ocean was made to enter it, and, by union with its substance, was thought to have been suffering loss in the long past and to be doomed to further losses yet to come. By a like union of the constituents of the air with the body of the earth, as time went on, the great smothering atmosphere of the primitive days was supposed to be brought down first to compatibility with marine life, later to the lower land life, and still later to the higher air-breathing forms.

Projected logically into the future, still further depletion of the vital constituents, even to the verge of exhaustion, attended with pauperisation and finally with extinction of life, entered into the forecast. With the gathering of the oceans more and more into the basins, and their absorption into the body of the earth, with the persistent consumption of the atmosphere, and with the progressive cooling of the whole, the moisture of the air was thought also to have grown less and less. At first a deep, warm mantle of vapour and cloud hypothetically clothed the whole earth, and even half-way down the geologic ages was thought to have enshrouded the globe and to have given warm, sultry climates to all latitudes. But this mantle at length was made to give place to rifted clouds and clearer skies, and later on to mild aridities, followed at length by desert stages, which are even now supposed to be creeping out persistently on the once fertile lands. Thus we reach our own times at a putative stage when heat and air and moisture are running low; thus the predestined end is foreshadowed in the not distant future.

The round conception of the history shaped it as a progress from excess to emaciation, a sliding down the scale; it made the life-history but an episode intercurrent in the great decline from the too hot and the too much to the too cold and the too little.

The logic in all this is plausible. Starting with the hypothetical premises, the conclusions seem to follow. Variations of detail might well be found in the complexities of the case. Especially might sources of supply be assigned to offset waste and loss in some degree, but, granting the premises, the conclusion is not easily escaped. In point of fact, the general conception dominated the geologic thought of the last century. Not only this, but in no small degree it gave direction to the interpretations, and

¹ Address delivered at Boston, Mass., on December 27, 1909, by the retiring president of the American Association for the Advancement of Science, Prof. T. C. Chamberlin.

in some measure even influenced the observations of geologic phenomena well down to the close of the century, and is far from obsolete to-day.

But, logical and plausible as was this general conception of earth-history, it was hung, as you have not failed to notice, on the hypothesis of the genesis of the earth accepted. However logical, its logical strength was only that of the hypothesis on which it was hung. I say its *logical* strength advisedly, for outside the logic of the general concept there was always the appeal to the concrete evidences of the geologic record. This appeal was made, and was thought to be on the whole confirmatory. The strata of high latitudes were found to contain relics of life of tropical or subtropical types, not only in the early stages, but well down toward recent times. Figs and magnolias grew in Greenland as late as the Tertiary period. Phenomena so striking gave deep hold to the logical scheme. Phenomena not so consonant with it were easily overlooked or lightly passed by, as is our wont when too much impressed by what *must* be true. It is, however, a merit of modern science that it puts that which is to the front, and that which logically *must* be in a secondary place; and so, during the past century, inconsonant data were gathered with the consonant. Most of the inconsonant facts were of the unobtrusive sort, but yet some of them were startling, were seemingly incredible, were indeed long doubted, and only slowly gained credence. The accumulation of this inconsonant data gradually weakened the hold of the general logical concept and prepared the way for a reconsideration.

Meanwhile a serious source of doubt had arisen on the logical side, from the progress of physics. The older hypotheses of the origin of the earth had been framed before the kinetic theory of gases was evolved. After the kinetic view was accepted, it was pointed out by Johnstone Stoney that the velocities of the molecules of the outer air place a limit to the volumes which planetary atmospheres may possess. When the test which this suggested was applied to the postulated atmospheres and voluminous gaseous states of the early earth, it gave rise to grave doubt as to the physical consistency of these conceptions.

Weakness also arose in another quarter. One of the main props of the gaseous or quasi-gaseous hypotheses was, as already remarked, the general conviction, based on dynamical grounds, that condensation from any other nebulous state than the gaseous or quasi-gaseous would give revolutions and rotations to the planetary system at variance with those actually possessed. A re-examination, however, near the close of the century, developed grounds for the conviction that a gradual gathering in of matter from a scattered orbital state would give rotations and revolutions quite as well in accord with the facts formerly known, and seemingly even better in accord with new facts recently brought to light.

Thus toward the close of the last century there arose from different quarters cogent reasons for a reconsideration of the prevailing general view, and with it a recast of the former forecast. Further scrutiny added new doubts to those that had previously arisen, and in the end the verity of the older hypotheses of genesis was challenged, and new conceptions, based on orbital dynamics, in contrast to gaseous dynamics, were offered in their stead.

It is not appropriate for me to say that this challenge was successful, or that the older conceptions of the earth's origin are to be laid on the shelf. As an advocate of the method of multiple working hypotheses, it belongs to me to beg of you to save and to use, so far as you can find use in them, all the hypotheses that seem to you to be capable of working at all. Much less would it be appropriate for me to affirm that any form of the newer conceptions is entitled to take the place of the older in your complete confidence. The final adjudication of genetic hypotheses can only come of long and patient trial by searching analysis, by scrutinising logic, and by application to the multitudinous phenomena which the earth, not only, but the solar and stellar systems, present. It is sufficient warrant for the present review, however, that not a few of the more incisive students of these things have been led seriously to reconsider the foundations of the hypothesis of earth-genesis that have been offered, old and new, and to examine with renewed care the interpretations and inferences that have been made to hang upon them. Whatever

may be your personal leanings, you will, no doubt, agree that it seems less laudable now to hang prophecies of the future upon hypotheses of genesis than when certain of these hypotheses received the almost universal assent of those then best qualified to hold opinions respecting them.

It does not seem to be going too far, moreover, to say that, whereas we seemed to be shut up to hypotheses of genesis that gave the earth a gaseo-molten state at the start, it now seems, to some students at least, possible that the earth inherited a quite different state from a slow growth from planetesimal or other accretions. If diverse views are thus permissible, they offer alternative working conceptions, and thus help to give freedom of interpretation while they stimulate observations on the critical phenomena. We may, therefore, be permitted first to review the states assigned the early earth by the competitive genesis offered, and then the critical phenomena that bear upon the earth's future.

Quite in contrast with the older pictures of a primitive earth cooling from a gaseous state, the planetesimal hypothesis, which may be taken as representative of theories based on concentration from a dispersed orbital state, postulates a solid earth growing up slowly by accretions, and becoming clothed gradually with an atmosphere and a hydrosphere. Each of the fundamental parts, the earth, the air, and the water, is made to grow up thus together from smaller to larger volumes without necessarily attaining at any stage a very high temperature. The early sources of growth for the atmosphere and the ocean, though reduced in later time, continued to serve as sources of replenishment when the familiar agencies of loss came into play in the later ages. Thus, far from assigning at the start a vast atmospheric and oceanic supply, and assuming progressive depletion of this with the progress of time, the newer view starts with a minimum supply and rests on means of feeding which are held to run hand in hand with the sources of loss and more or less completely to compensate them in a varying way. The question of the future under this view is, therefore, not how long beyond the present day will the original supply last, but rather how long will the oscillating compensation of loss and supply remain effective? Or, in other words, how long will the past degree of equilibrium between the opposing agencies keep the critical conditions within the limits required by life? This question turns us quite away from any serious dependence on the original states, and centres attention on the geologic record and on the potency of agencies still in action. Are the chief agencies which have controlled life conditions for tens of millions of years past still in good working order and likely to continue effective for a long era yet to come, or do they show clear signs of declining power portending an early failure? Let us enter a little closer into the consideration of the specific factors on which life depends, though time will not permit us to go far.

The pre-scientific fear that the end of life will come by cataclysm is not yet obsolete, nor is it theoretically impossible, but violent agencies are among the least to be feared. Life might, indeed, be imagined to be in jeopardy from volcanic and seismic convulsions, but they really offer no serious menace to life in general, and appear never to have done so in the known ages. The deadliness of these boisterous catastrophes impresses itself unduly on the emotions. The real peril, if peril there be, lies in the deadly unbalancing of agencies of the quiet sort.

The conditions essential to the maintenance of the habitability of the earth are many, but the more critical factors either lie in the atmosphere itself or are intimately associated with it. The point of keenest interest is the narrowness of range to which these mobile factors are confined. The several constituents of the atmosphere might each or all easily be too scant or too abundant. In a peculiar sense is this true of the carbon dioxide, which, though one of the least, is pre-eminently the decisive constituent of the atmosphere. A small proportion of carbon dioxide is essential to plant life, and so to animal life, while a large proportion would be fatal to air-breathing animals. If the three or four hundredths of one per cent. now present were lost, all life would go with it; if it were increased to a few per cent., the higher life would be suppressed or radically changed; and yet, on the one hand, the theoretical sources of supply are abundant, while,

on the other, the agencies of depletion are efficient and active. There is little escape from the conclusion that, ever since the birth of air-breathing life, some 30,000,000 or 40,000,000 years ago, let us say, the interplay of these agencies of supply and depletion has been so balanced that neither fatal excess, nor fatal deficiency has been permitted to cut short the history of the higher life.

The dangers of excess or deficiency of the other constituents of the air are, indeed, less narrow when named in percentages, but they are scarcely less real in theoretical possibility.

The well-being of life is hemmed in between a suitable proportion of moisture in the air dependent on a competent area of water-surface to supply it, on the one hand, and a diluvial excess of water, on the other. Universal deluges and universal deserts would alike be disastrous. A few thousand feet more of water-depth or a few thousand feet less would alike seriously restrict the class of life to which we belong.

In even a more serious way the habitability of the earth is conditioned on a narrow range of mean temperature—a range, roundly speaking, of 100° Centigrade. This is scarcely 5 per cent. of the range of natural temperatures on the earth, and a still smaller per cent. of the range of temperatures in the heavens. A few miles above us and a few miles below us fatal temperatures prevail. It is profoundly significant that the thermal states of the narrow zone of life on the face of the earth should have been kept within so close variations as to permit the millions of species forming the great genealogical lines leading up from the primitive types to have perpetuated their lineages in unbroken continuity for such ages, while the prevalent temperatures a few miles above them or a few miles below them, as well as in space generally, would have been fatal. While the necessary heat is dependent on the sun, this control of temperature seems to have been intimately related to the atmosphere, and is a further index of its specially critical functions.

To appreciate the full significance of the control of life conditions within these narrow limits when the possibilities were so free and so wide, there is need for some tangible index of the time, but there are at present no means for the close measure of the geologic ages, merely rough estimates of the order of magnitude. Life was far advanced when a readable record first began to be made; but yet, since that record began, at least 100,000 feet of sediments—not to choose the largest estimates—have been laid down by the slow methods of wash from the land and lodgment in the basins. The estimate of the years thus represented has been put variously from 50,000,000 to 100,000,000, with, indeed, higher figures as well as lower. Merely to scale roughly the order of magnitude, and without pretence of accuracy, let us take the midway figure of 75,000,000 years as representative. Let this be divided into fifteen periods of 5,000,000 years each, and these will roughly represent the technical "periods" of geologists. By this rough scale we may space out such of the great events as we need now note.

Slight and changeable excesses of evaporation over precipitation and the reverse prevail widely, but only intense and persistent aridity gives rise to thick deposits of salt, gypsum, and other evaporation products over large areas—with perhaps some exceptions—for in nearly all large natural basins the area that collects rainfall is notably larger than the closed basin within it that alone can retain water for continuous evaporation. It is, therefore, fairly safe to infer clear skies and pronounced aridity when beds of salt and gypsum occur over large areas, especially if accompanied by appropriate physical characters and by such types of life only as tolerate high salinity or show pauperisation, or by a total absence of life.

Now extensive deposits of salt and gypsum are found in the Salt Range of India, in strata of the Cambrian period, the earliest of the fifteen that make up our rough scale of 75,000,000 years. Because these lie so near the beginning of the geologic record, they afford a singularly instructive insight into the conditions of the atmosphere well back toward its primitive state. They challenge at once the view that in those early ages the earth was swaddled by a dense vaporous atmosphere from pole to pole; for under such a vaporous mantle a great desert tract in India would be scarcely credible.

If we come forward in time two periods, to the deposits of the Silurian stage, we find that, underlying the basin of the St. Lawrence in New York and westward, there stretch great sheets of salt and gypsum, many thousand square miles in extent. These beds are accompanied by complete barrenness of life in some parts, by pauperisation of life in other parts, by selections of life according to tolerance of salinity in still other parts, and by harmonious physical characters, all of which combine to add strength to the interpretation. All these imply a degree of aridity approaching desert conditions in what is now the well-watered region of our Great Lakes. These signal facts join those of the Salt Range of India of earlier date in challenging the former conception of a universal envelope of vapour and cloud in all those early times.

In the next period there are formations that have been interpreted as implying desert conditions, but perhaps on less firm grounds, and we pass on to certain stages in the Sub-Carboniferous period next following, wherein beds of salt and gypsum are found in Montana, Michigan, Nova Scotia, and Australia, which imply like climatic conditions. If we pass on to the Permian and Triassic periods, near the middle of the geologic series, beds of salt and gypsum are phenomenally prevalent on both the eastern and western continents, reaching through surprising ranges of latitude. The relative paucity, as well as the peculiar characteristics of the life of those times, seems equally to imply vicissitudes of climate in which scant atmospheric moisture was a dominant feature. There seems no tenable way to interpret these remarkable facts of the middle periods except by assuming an even greater prevalence of aridity than obtains at the present time. So, at times in the later periods, but at times only, the stratigraphic record implies atmospheres as arid as that of to-day, not everywhere, indeed, but in notable areas and in certain horizons.

These and other significant facts of consonant import form one group of phenomena.

If, on the other hand, the record be searched for facts of opposite import, they will come easily to hand. Starting near the beginning of the record, it is even more easy to find stages abounding in evidences of prevailing humidity, of great uniformity of climate, and of most congenial life-conditions reaching through wide ranges of latitude. If we rested on this selection alone, the old view would be abundantly sustained, but the strata bearing evidences of aridity lie between these. Combining the two sets of facts, the conception seems to force itself upon us that from the very earliest stages of the distinct life-record onward, there have been times and places of pronounced aridity much as now, or even more intense, while at other times, intervening between these, more humid and uniform conditions prevailed.

This conception grows in strength as we turn from atmospheric states to prevailing temperatures. The body of scientific men have rarely been more reluctant to accept any interpretation of geologic phenomena than that of recent general glaciation on the lowlands of Europe and America in mid-latitudes when that view was first advanced by Louis Agassiz. With the conception of former pervasive warmth then prevalent, it seemed beyond belief that great sheets of ice could have crept over large portions of the habitable parts of Europe and North America some thousands or tens of thousands of years ago. Belief in this was made easier, however, by the view also then prevalent that the earth had been greatly cooled in the progress of the ages, that the atmosphere had been much depleted by the formation of coal, of carbonates, and of oxides, that the ocean had been reduced by hydration and entrance into the earth, and that thus a stage had been reached that made possible an epoch of depressed temperature and of glaciation. The Ice age, thus theoretically associated, came to be widely regarded as but the first stage in a series of secular winters destined to lead on to the total refrigeration of the earth. This view was abetted by the theory of a cooling sun. The depleting and the cooling processes were regarded as inevitably progressive, and the final doom of the earth as thus foreshadowed in the near future, geologically speaking.

But opinion was scarcely more than adjusted to this view when the geologists of Australia, of India, and of South Africa, severally and independently, and later those of South America, presented evidences of former glaciation.

over extensive areas in those low latitudes. The typical marks of glaciation were, indeed, traced even up to and a little across the tropical circles from the south, in Australia, and from the north, in India. Moreover, all these were reported from strata of Permian or late Carboniferous times, *i.e.* from the sixth or seventh of the technical "periods." For a score of years the body of geologists, not in immediate contact with the evidence itself, doubted the interpretation, but the growing evidence grew at length to be utterly irrefutable. There seems no rational escape from the conclusion that mantles of ice covered large areas in the peninsula of India, in Australia, in the southern part of Africa, and in South America, close upon the borders of the tropics, at a time roundly half-way back to the beginning of the readable record of life.

On the basis of similar evidence, Strahan and Reusch have announced glacial beds in Norway at a horizon much lower but not closely determinate. Willis and Blackwelder have described glacial deposits of early Cambrian age in the valley of the Yangtse, in China, in latitudes so low as 31°. Howchin and David have described glacial formations of similar age in Australia. In the last two cases the glacial beds lie below the strata that bear the Cambrian trilobites; in other words, they lie at the very bottom of the fossil-bearing sediments, fifteen periods back, or 75,000,000 years ago on our rough scale. Prof. Coleman has offered what he deems good evidence of glaciation much farther back at the base of the Huronian, in Canada, but some scepticism as to its verity has yet to be overcome.¹

Even more pointedly than the epochs of aridity do these early epochs of glaciation seem incompatible with the view of a hot earth universally wrapped in a vaporous mantle in early times. They favour the alternative view of merely temporary localised intensifications of climate which life was able repeatedly to survive. This seems to warrant the belief that life may survive similar intensifications again and again in the future.

At present polar and alpine glaciation are contemporaneous with aridity. There are reasons for thinking that the past glaciations and aridities were in some similar way correlated, and that they cooperated to give ricissitude to the climates of certain geologic epochs. The known epochs of glaciation, however, are fewer than those of aridity.

On the other hand, at several stages, as already noted, abundant life, bearing all the evidences of a warm-temperate or subtropical character, flourished in high latitudes. In Greenland, Spitsbergen, and other Arctic islands, are found the relics of life not known to be able to live except under conditions of genial warmth. These imply former subtropical conditions where now only frigidities reigns.

In the light of these contrasted climatic states of aridity and glaciation on the one hand, and of uniformity and geniality in high latitudes on the other, intervening between one another, we seem now forced to the conception of profound climatic alternations, extending over the whole stretch of known geologic time. Concurrent with these alternations, there may, perhaps, have been variations in the constitution, as there certainly were in the condition, of the atmosphere.

If we turn to the relations of the waters and the land, an analogous oscillating history presents itself. This was possibly connected causally with the climatic oscillations. At no time in the history recorded by clear geologic testimony is there proof of the absence of land, and certainly at no time is there a hint of the absence of an ocean, whatever theoretic views may be held of the earliest unknown stages.

The progress of inquiry seems to force the conviction that the land area in the earliest stages of good record was quite comparable to that of the present time, both in its extent and in its limitations. Following down the history, the land area seems at certain times to have been larger than now, while at other times it was smaller. There appears to have been an unceasing contest between the agencies that made for the extension of the land and the agencies that made for the extension of the sea. While each gained temporarily on the other, complete victory

never rested with either. From near the beginning of the readable record there appears to have been an unbroken continuity of land life, and, from a like early stage, an unbroken continuity of marine life. Probably the history of both goes back unbroken into the undeciphered eras which precede the readable record, and no one to-day can safely affirm the precedence of either over the other, either in time or in genesis, whatever his theoretic leanings may be.

Among the agencies that may be assigned for the extension of the land are those that deform the body of the earth, deepening its basins and drawing off the waters, while other portions are protruded and give renewed relief and extent to the land. Among the agencies that make for the extension of the sea are the girdling of the waves about the borders of the land, and the decay and wash of land surface, which is thus brought low at length and covered by the advancing waters. If the deformation of the earth-body were held in abeyance for an indefinite time, the lowering of the land, the filling of the basins, and the spreading of the sea would submerge the entire land surface and bring an end to all land life. Great progress in such sea-transgressions appears to have been made again and again, until perhaps half the land was submerged, but before land life was entirely cut off, or even very seriously threatened, a regenerative movement in the body of the earth intervened, the land was again extended, and the sea again restricted. Here then, also, there has been a reciprocal movement, which, while it has brought alternate expansions of land life and of sea life, has, notwithstanding, permitted the preservation of both, and thus maintained the continuity of the two great divisions of life.

It appears, thus, that in each of the great groups of terrestrial conditions upon which life is dependent, there has been, through the known ages, vast as they are, an oscillatory movement which has brought profound changes again and again, but has never permitted any of the disasters threatened in these movements to go far enough to compass the universal extinction of life. These reciprocal movements appear to be dependent upon a balancing of the action of agencies that is scarcely less than a law of equilibrium. It is not too much to regard this as a regulative system. A clear insight into the agencies of this regulative system is rather a task of the future than an attainment of the present, and I can only offer tentative hints of what may prove to be its main factors, and beg of you to accept them with due reserve.

The preservation of the land against the incessant encroachments of the waters seems probably due to a periodic deformation of the earth-body dependent on internal dynamics not yet well understood, at least not yet demonstrated to general satisfaction. The body of the earth feeds its atmosphere through volcanic and other means. How far this is merely a return of what has been absorbed earlier it is not prudent here to say, as opinion is not harmonious on this, and the evidence is as yet uncertain. Much depends on the constitution of the earth's interior, and that in turn hinges on its mode of origin. Perhaps it will be agreed generally that feeding from the interior is one of the sources of supply which offsets the depletion of the atmosphere caused by its union with earth substance, in short, that the earth-body gives out as well as takes in atmospheric material. Important or unimportant as this may be, it is not apparent that there is in it any automatic balancing suited to control the delicate adjustments requisite for continuity of life. The ocean acts as an important regulator by alternately absorbing and giving out the atmospheric gases as required by the state of equilibrium between the water and the air. This action is automatic, but has its limitations and peculiarities, and does not seem wholly adequate. If we are able to name such an adequate automatic action at all at present, it probably lies in the molecular activities of the terrestrial and solar atmospheres, and in the relations of these to the gravitative powers of the earth and the sun.

If analysis of the molecular action of the outer atmosphere be pushed to its logical conclusions, it leads to the conception of supplementary atmospheres, in part orbital, filling, in an attenuated way, the whole sphere of the earth's gravitative control. A similar study of the sun's atmosphere suggests a similar supplementary extension; and this extended portion surrounds and embraces the earth's

¹ Later evidence has removed this from many minds, including that of the speaker.

atmosphere. Under the laws of molecular activity these two atmospheres must be interchanging molecules at rates dependent on the conditions of equilibrium between them. It is reasonable that an excess in the earth's atmosphere should cause it to feed out into the sun's sphere of control more than it receives, and that a deficiency in the earth's atmosphere should cause more feeding in from the sun's supplementary atmospheres than the earth gives out. If this conception be true and be efficient, the maintenance of the delicate atmospheric conditions required for the continuity of life is automatically secured. The failure of our atmospheric supply is thus made to hang, not simply on the losses and gains at the earth's surface, but on the solar interchange, and hence on the solar endurance.

The sun is giving forth daily prodigious measures of energy. The endurance of the sun is not, however, merely a question of unrequited loss, for it gains energy and substance daily as well as loses, and, so far as present knowledge goes, its gain is greatly inferior to its loss. So long as the heat of the sun was supposed to be dependent on ordinary chemical changes, or on the fall of meteorites, or on self-contraction, an activity adequate for terrestrial life could only be estimated at a few million years. But recent discoveries in radio-activity have revealed sources of energy of an extremely high order. In the light of these the forecast of the sun's power to energise the activities of the atmosphere dependent on it, and to warm the earth, is raised to an indeterminate order of magnitude.

If we may thus find grounds for a complacent forecast in reciprocal actions on the earth and in reciprocities between the earth and the sun, are we free from impending dangers in the heavens without?

Present knowledge points to one tangible possibility of disaster—collision with some celestial body, or close approach to some sun or other great mass, large enough to bring disaster by its disturbing or disruptive effects. Within the solar system, the harmonies of movement already established are such as to give assurance against mutual disaster for incalculable ages. Comets pursue courses that might, theoretically at least, bring about collision, but do not appear usually to possess masses sufficient to work complete disaster to the life of the earth even should collision occur, whatever local disaster might follow at the point of impact. The motions of the stars, however, lie in diverse directions, and collisions and close approaches between them are theoretically possible, if not probable, or even inevitable. There are also in the heavens nebulae and other forms of scattered matter, and doubtless also dark bodies, which may likewise offer possibilities of collision. The appearance of new stars flashing out suddenly and then gradually dying away suggests the actual occurrence of such events. It has been even conceived that the close approach of suns is one of the regenerative processes by which old planetary systems are dispersed and new systems are brought into being. One phase of the planetesimal hypothesis is built on this conception, and postulates the close approach of some massive body to our ancestral sun as the source of dispersion of a possible older planetary system, and the generation of the nebulous orbital conditions out of which our present system grew. However this may be, it must be conceded that in collision and close approach lie possibilities, if not probabilities, of ultimate disaster to the solar system and to our earth. But here, as before, the vital question lies in the time element. How imminent is this liability? The distances between stars are so enormous that, though they move diversely, the contingencies of collision or disastrous approach are remote. Nothing but rough computations based on assumptions can be made, but these make disaster to a given sun or system fall, on the average, only once in billions of years. There is no star the nearness of which to us, or the direction of motion of which is such as to threaten the earth at any specific period in the future. There is only the general theoretical possibility or probability. While, therefore, there is to be, with little doubt, an end to the earth as a planet, and while, perhaps, previous to that end conditions inhospitable to life may be reached, the forecast of these contingencies places the event in the indeterminate future. The geologic analogies give fair grounds for anticipating conditions congenial to life for millions or tens of millions of years to come, not to urge the even larger possibilities.

But congeniality of conditions does not ensure actual

realisation. There arise at once questions of biological adaptation, of vital tenacity, and of purposeful action. Appeal to the record of the animal races reveals in some cases a marvellous endurance, in others the briefest of records, while the majority fell between the extremes. Many families persisted for millions of years. A long career for man may not, therefore, be denied on historical grounds, neither can it be assured; it is an individual race problem; it is a special case for the problem of the races in the largest sense of the phrase.

But into the problem of human endurance two new factors have entered, the power of definite moral purpose and the resources of research. No previous race has shown clear evidence that it was guided by moral purpose in seeking distant ends. In man such moral purpose has risen to distinctness. As it grows, beyond question it will count in the perpetuity of the race. No doubt it will come to weigh more and more as the resources of destructive pleasure, on the one hand, and of altruistic rectitude, on the other, are increased by human ingenuity. It will become more critical as the growing multiplicity of the race brings upon it, in increasing stress, the distinctive humanistic phases of the struggle for existence now dimly foreshadowed. It will, beyond question, be more fully realised as the survival of the fittest shall render its verdict on what is good and what is evil in this realm of the moral world.

But, to be most efficient, moral purpose needs to be conjoined with the highest intelligence, and herein lies the function of research. None of the earlier races made systematic inquiry into the conditions of life, and sought thereby to extend their careers. What can research do for the extension of the career of man? We are witnesses of what it is beginning to do in rendering the forces of nature subservient to man's control and in giving him command over the maladies of which he has long been the victim. Can it master the secrets of vital endurance, the mysteries of heredity, and all the fundamental physiological processes that condition the longevity of the race? The answer must be left to the future, but I take no risk in affirming that when ethics and research join hands in a broad and earnest endeavour to compass the highest development and the greatest longevity of the race, the era of humanity will really have begun.

FORTHCOMING BOOKS OF SCIENCE.

AGRICULTURE.

D. Appleton and Co.—The Story of Sugar. G. T. Surface, illustrated. *Constable and Co., Ltd.*—Soils and Manures, J. A. Murray. *Duckworth and Co.*—Agricultural Bacteriology, J. Percival, illustrated; and a new edition of *Agricultural Botany*, J. Percival, illustrated. *The Gresham Publishing Company.*—The Standard Encyclopedia of Modern Agriculture and Rural Economy, vols. viii. to xii., illustrated. *Macmillan and Co., Ltd.*—Barthel's Method for the Examination of Milk and Milk Products, translated by W. Goodwin; Improvement of Wheat and other Cereals, Prof. R. H. Biffen.

ANTHROPOLOGY.

Macmillan and Co., Ltd.—Totemism and Exogamy: a Treatise on certain Ancient Forms of Superstition and Society, Dr. J. G. Frazer, with maps, 4 vols. *Methuen and Co.*—The Negro in the New World, Sir H. H. Johnston, illustrated. *Milner and Co., Ltd.*—Prehistoric Man, J. McCabe, illustrated. *Swan Sonnenschein and Co., Ltd.*—Bushman Folk-lore, L. C. Lloyd, edited by Dr. G. M. Theal, illustrated; History and Ethnography of South Africa before 1795, Dr. G. M. Theal, vol. iii., the Dutch Portuguese, Hottentots and Bantu to September, 1795.

O'Donahue. *Longmans and Co.*—A History of the Cavendish Laboratory, Cambridge. This volume is intended to commemorate the twenty-fifth anniversary of the election of Sir J. J. Thomson to the Cavendish professorship of experimental physics. Among the contributors are the President of Queens' College, Dr. Schuster, W. C. D. Whetham, Dr. R. T. Glazebrook, Sir J. J. Thomson, Prof. H. F. Newall, Norman Campbell, Prof. E. Rutherford, C. T. R. Wilson, and Prof. Wilberforce. The final chapter of the book will be devoted to a bibliography and biography of those who have done research work at the laboratory since its foundation. *Macmillan and Co., Ltd.*—Tennyson as a Student and Poet of Nature, Sir Norman Lockyer, K.C.B., F.R.S., and Winifred L. Lockyer. *Oxford University Press.*—Chinese Pottery and Porcelain, a translation of the Tao Shuo, with introduction, &c., by S. W. Bushell. *G. Routledge and Sons, Ltd.*—Sonnenschein's Best Books, new edition, in three parts. *Swan Sonnenschein and Co., Ltd.*—Hegel's Phenomenology of Mind, translated by J. B. Baillie, 2 vols.; Thought and Things: a Study of the Development and Meaning of Thought or Genetic Logic, Prof. J. M. Baldwin, in 3 vols., vol. iii., Real Logic; Time and Free Will: an Essay on the Immediate Data of Consciousness, Prof. Bergson, translated by F. L. Pogson; Physiological Psychology, Prof. W. Wundt, a translation of the fifth and wholly re-written German edition by Prof. E. B. Titchener, in 3 vols., vol. ii. *Truslove and Hanson, Ltd.*—Oriental Silverwork, H. Ling Roth, illustrated. *The University Tutorial Press, Ltd.*—Hygiene for Training Colleges, Dr. R. A. Lyster.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

BIRMINGHAM.—The Huxley lecture this year is to be delivered by Prof. Percy Gardner, Lincoln and Merton professor of classical archaeology in the University of Oxford.

Mr. Joseph Coates has been appointed to a demonstratorship in chemistry, and Mr. R. H. Whitehouse assistant, in the Day Training College for Men.

CAMBRIDGE.—The next combined examination for sixty-seven entrance scholarships and a large number of exhibitions at Pembroke, Gonville and Caius, King's, Jesus, Christ's, St. John's, and Emmanuel Colleges will be held on Tuesday, December 6, and following days. Mathematics, classics, and natural sciences will be the subjects of examination at all the above-mentioned colleges. Most of the colleges allow candidates who intend to study mechanical sciences to compete for scholarships and exhibitions by taking the papers set in mathematics or natural sciences. A candidate for a scholarship or exhibition at any of the seven colleges must not be more than nineteen years of age on October 1, 1910. Forms of application for admission to the examination at the respective colleges may be obtained as follows:—Pembroke College, W. S. Hadley; Gonville and Caius College, the Master; King's College, W. H. Macaulay; Jesus College, A. Gray; Christ's College, Rev. J. W. Cartmell; St. John's College, the Master; Emmanuel College, the Master, from any of whom further information respecting the scholarships and other matters connected with the several colleges may be obtained.

OXFORD.—The University Junior Scientific Club will hold its triennial conversazione on Tuesday, May 24, being the Tuesday in "Eights Week." Members of the club can obtain tickets on application to Mr. N. T. Huxley, Balliol College. The promise of exhibits from members will be gratefully welcomed by Mr. A. F. Coventry, Magdalen College, on behalf of the committee. It is hoped that many old members of the club will take the opportunity of re-visiting the scientific departments of the University.

THE late Mr. E. S. Massey, of Rochdale, among many other bequests, has left 6800*l.*, free of duty, to the University of Manchester. The residue of his property, amounting to about 110,000*l.*, after the bequests are provided for, is left upon trust to be applied for such charitable purposes for the benefit of the inhabitants of Burnley as the Corporation of Burnley shall determine, but so that such purposes be limited to all or one or more of the following objects, and be not by way of reduction of rates:—education, whether mental, physical, technical, or artistic, the advancement of science, learning, music, or other art.

An effort is being made to found a National Industrial Education League to emphasise the necessity of making elementary education go hand in hand with industrial training. In view of the general consensus of opinion as to the necessity for the formation of such a league, a national conference is to be called at an early date for the purpose of formulating a scheme for carrying out the objects of the league. In addition to the approval of many other associations of workers, no fewer than 88 trades' councils, together representing 334 towns and 299 trades, have given their adhesion, and the London Chamber of Commerce recently passed unanimously the following resolution:—"That the council of the chamber approve, heartily support, and will give all their assistance to the proposed National Industrial Education League." Anyone anxious to take part in the work of the new league should communicate with Mr. R. Applegarth, Central Offices, Craig's Court House, Charing Cross, London.

MR. W. H. LEVER, who was appointed recently chairman of the Liverpool School of Tropical Medicine, in succession to the late Sir Alfred Jones, has made known to the council and professors of the University of Liverpool the particulars of a munificent scheme he has devised to assist the work of the University. He proposes to devote the sum of 91,000*l.* to the scheme. Arrangements have been made with the owners of the old Bluecoat School for a lease for a number of years. During that period the University can have the option of purchasing the school for a sum, approximately, of 24,000*l.* Any time when the University exercises that option Mr. Lever will pay the money, and the school will be furnished. If the building is not found suitable, then he will pay 24,000*l.* for the erection of a building adjoining the University, in which the School of House and Town Planning can be accommodated, and also the School of Architecture. While the University is considering whether the option shall be exercised, Mr. Lever will pay the rent of the school. To provide money for the School of House and Town Planning, the School of Tropical Medicine, and the School of Russian Studies, Mr. Lever proposes to transfer 60,000*l.* worth of shares in the Bromboro' Port Estate Company to the University. These shares will in future years be a source of great income to the University. While the shares are not paying a dividend, Mr. Lever has arranged for ten years to guarantee 3 per cent. on the 60,000*l.*, which will make 1800*l.* a year for ten years. With the consent of the University, of this 1800*l.* a year 800*l.* will go to the School of Civic Design, 800*l.* to the School of Tropical Medicine, and 200*l.* to the School of Russian Studies.

ON Friday last, March 4, the Chancellor of the Exchequer, with whom were Mr. Haldane and Mr. Runciman, received in his private room at the House of Commons a deputation from various universities on the subject of increased financial assistance. A news agency states that the deputation represented all the universities and university colleges in England, excepting Oxford, Cambridge, and Durham. The proceedings were private, but the *Times* gives the following account of the points brought forward by the deputation. It was urged that money is greatly needed for development purposes. The Treasury grants, so far from cutting off local subscriptions, municipal and private, have encouraged them, local people feeling that the institutions are recognised by the Government and regarded as a national concern to which they may well contribute. Every new chair established and every new building put up means extra expense for maintenance, and the deputation urged that, while it is quite possible to get the locality to provide buildings and equipment, it cannot

provide maintenance. Many localities feel they have done all they can, and they also feel they are not merely doing local work, but national and Imperial, indeed, world-wide work. Students are drawn from every part of the Empire and from foreign countries, particularly China and Japan, and they are under no obligation to give their services where they are trained. Any increased grant now given by the nation will be used, not in the fixed and ordinary work of the institutions, but in the highest class of work and in various enterprises that are being kept back for want of funds. The speakers also pointed out that there is under present conditions a certain amount of wastefulness, not in money, but in brains and energy, because at their meetings the authorities are generally occupied, not in discussing how best to spend the money and what undertakings will be best for the country, but merely how to economise their funds and how to save 10*l.* or 50*l.* Work is lying ready at hand which they are powerless to undertake. Mr. Lloyd George, in the course of a sympathetic reply, told the deputation they could not have come at a worse time. Nothing definite was settled, but a committee has been appointed by the deputation to prepare more detailed information for the Chancellor of the Exchequer as to the financial requirements of the various institutions.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, January 27.—Sir James Dewar: Long-period determination of the rate of production of helium from radium. In a previous communication the rate of the production of helium from 70 milligrams of radium chloride was determined by a succession of observations on the growth of pressure measured by a McLeod gauge. These observations extended over a period of about six weeks. It was thought desirable to make an experiment to determine the amount of helium resulting from this same sample of radium, after standing in a sealed bulb for an extended period. For this purpose the bulb containing the radium chloride was sealed off at the conclusion of the above-mentioned experiment of 1908 and kept for nine months. In order to measure the helium thus produced it was necessary to devise a vacuum-tight joint between the sealed radium bulb and a McLeod gauge so constructed that, after thoroughly exhausting the gauge, the drawn-out end of the radium bulb could be broken off, thus allowing the pressure of the accumulated helium in the radium bulb to be rapidly determined. The total volume of the apparatus was 320 c.c. The pressure in the radium bulb when sealed off at the conclusion of first experiment was 0.00406 mm., the partial pressure due to this amount of helium would be 0.00008 mm., which must be deducted from the observed pressure to get the true pressure due to the helium produced in the radium bulb during the period in which it remained sealed up; also the pressure in the gauge, before breaking (0.00005 mm.), must also be deducted. This gives a corrected pressure of 0.01613 mm., obtained after heating the salt, due to the helium produced from 70 milligrams of pure radium chloride during a period of 275 days, in a space the total volume of which was 320 c.c. The value of the rate in terms of cubic millimetres of helium per gram of radium per day is thus deduced as 0.463.

March 3.—Sir Archibald Geikie, K.C.B., president, in the chair.—T. G. Bedford: The depression of freezing point in very dilute aqueous solutions.—J. Mercer: Sturm-Liouville series of normal functions in the theory of integral equations. It is the purpose of this memoir to develop the theory of Sturm-Liouville series of normal functions as a branch of the theory of integral equations. In the first place, two theorems are established relative to the series

$$\psi_1(s) \int_a^b \psi_1(t) f(t) dt + \psi_2(s) \int_a^b \psi_2(t) f(t) dt + \dots \\ + \psi_n(s) \int_a^b \psi_n(t) f(t) dt + \dots,$$

in which $\psi_1(s), \psi_2(s), \dots, \psi_n(s), \dots$ are a complete system of normal functions corresponding to a function $(K(s, t))$ of

positive type in the square Q defined by $a \leq s \leq b, a \leq t \leq b$: the normal functions are assumed to have such an order that the singular value corresponding to $\psi_n(s)$ does not decrease as n increases: no restriction is placed upon $f(s)$ beyond that it should have a Lebesgue integral in (a, b) . Denoting by $K_\lambda(s, t)$ the solving function corresponding to $K(s, t)$, the first theorem is to the effect that the upper and lower limits of indeterminacy of the above series include

$$\lim_{\lambda \rightarrow -\infty} -\lambda \int_a^b K_\lambda(s, t) f(t) dt$$

between them. According to the second

$$\lim_{\lambda \rightarrow -\infty} -\lambda \int_{(Q)} K_\lambda(s, t) f(s) f(t) (ds dt)$$

exists and is equal to the sum of the series

$$\left[\int_a^b \psi_1(t) f(t) dt \right]^2 + \left[\int_a^b \psi_2(t) f(t) dt \right]^2 + \dots \\ + \left[\int_a^b \psi_n(t) f(t) dt \right]^2 + \dots,$$

when the latter is convergent; whilst the limit is $+\infty$, when the series is divergent. It is then shown that, when $K(s, t)$ is the Green's function of

$$\frac{d^2 u}{ds^2} + q(s)u = 0$$

satisfying a pair of boundary conditions at the end points of $(0, \pi)$, an asymptotic formula for $K_\lambda(s, t)$ exists which permits the deduction of important theorems relative to the canonical Sturm-Liouville series

$$\psi_1(s) \int_0^\pi \psi_1(t) f(t) dt + \psi_2(s) \int_0^\pi \psi_2(t) f(t) dt + \dots \\ + \psi_n(s) \int_0^\pi \psi_n(t) f(t) dt + \dots$$

The normal functions $\psi_1(s), \psi_2(s), \dots, \psi_n(s), \dots$ are now solutions of

$$\frac{d^2 u}{ds^2} + (q(s) + \lambda)u = 0,$$

which, for suitable values of λ , satisfy the same pair of boundary conditions as $K(s, t)$; to particular systems of these functions correspond Fourier's sine and cosine series. The results obtained for any canonical Sturm-Liouville series are very similar to, but slightly more general than, those for the two particular series which are associated with the names of Fejér, Hurwitz, and Lebesgue. The fourth section of the memoir is devoted to an investigation of the convergence of canonical Sturm-Liouville series. In the course of this, it is shown that the convergence of any one of these series at a point of the open interval $(0, \pi)$ involves the convergence of all the other series which correspond to the same function $f(s)$. The memoir contains an extension of all results obtained for the canonical to the most general type of Sturm-Liouville series.—A. Von Antropoff: The solubility of xenon, krypton, argon, neon, and helium in water.—L. N. G. Filon: Measurements of the absolute indices of refraction in strained glass. If light be transmitted through a slab of glass under tension T in a direction perpendicular to the line of stress, it is broken up into two components, polarised in planes perpendicular and parallel to the line of stress. If μ be the index of refraction of the glass in the unstrained state, then, in the strained state, the indices of refraction corresponding to the above two components are $\mu + C_1 T$, $\mu + C_2 T$ respectively. The coefficients C_1, C_2 are spoken of as the stress-optical coefficients for the two rays. The present paper gives an account of measurements of C_1 and C_2 according to a method described by the author in Roy. Soc. Proc., A, vol. lxxix., pp. 440-2. The measurements have been carried out on two Jena glasses bearing catalogue Nos. O. 935 and VV. 3199 respectively, the first being a borosilicate, the second an "ultra-violet" glass. So far as is known, this is the first series of absolute measurements of C_1 and C_2 extending fairly continuously throughout the spectrum. The only previous measurements are due to Pockel (*Ann. d. Phys.*, 1902), and give the

ues of C_1 and C_2 for the sodium, thallium, and lithium es only, obtained by quite a different method. The fficients C_1 , C_2 are found to be negative, so that both s are accelerated by tension, but the effect is much ger for C_2 , i.e. for the ray polarised in the direction of ss. With regard to the dispersion in O. 935, both C_1 and C_2 show a slight general decrease as we move towards violet, but in VV. 3199, C_1 shows a decrease, whereas shows an increase. The above general variation is ken by a number of local oscillations, some of which well marked and confirm previous observations of $-C_1$ (Phil. Trans., A, vol. ccvii., pp. 293-301), whilst s are more doubtful; but it seems probable that both ces of refraction due to stress are affected locally by e periods of the constituents of the glass, causing gularities in the curves of C_1 and C_2 similar to those bited by the curve of the index of refraction in omalous dispersion.

Royal Microscopical Society, February 16.—Prof. J. A. omson, president, in the chair.—Prof. J. A. Thomson: es on *Dendrobrachia fallax*, a rare and divergent anti-harian.—A. A. C. E. Petrified material of Cordaites and other allied era, and also of Myeloxylon, has been obtained from Upper Coal-measures of Staple Hill, Bristol.

MANCHESTER.

Literary and Philosophical Society, January 25.— Francis Jones, president, in the chair.—Prof. W. W. H. e and F. Brotherton: The electrical resistance of the nan body. Measurements have been made with direct alternating currents, the hands of the subject being as uler immersed in solutions of common salt. Values of resistance in the first case are from 1000-2000 ohms, only from 700-800 ohms with alternating currents. The h values in the first case are due to polarisation, the nan body acting like a storage battery made up of con- centration cells. When a direct current is applied to the y the current falls for a time and then increases, there

being a gradual increase of polarisation during the first period, and a decrease of the body resistance during the second period. The maximum voltage for direct currents used in the experiments was about 40, which must be gradually introduced, and very gradually withdrawn, otherwise painful shocks are administered. It was found that the resistance is inversely proportional to the area of the surface of the wet skin. The ratio of the direct to the alternating values of the resistance is much higher when dry or nearly dry skin is tested. With the dry fingers applied to 100-volt direct current terminals the shock at the kathode is greater than at the anode, and enables the polarity of the terminals to be readily determined. With nearly dry fingers it is also easy to test polarities of circuits of less than 20 volts. This method is useful in practice. With about 10 volts and the fingers immersed in salt solutions containing metal elec- trodes, the body can be used as a telegraphic receiving instrument, the shocks at the kathode as the current is re- versed by a transmitting commutator enabling messages to be received by the usual code. The resistance of the body being relatively low when the skin is moist, precautions must be taken in using supply circuits, especially in chemical and other works. Electric-light fittings in bath- rooms, public baths, and medical baths require special precautions.

February 8.—Mr. Francis Jones, president, in the chair. —G. Hickling: The anatomy of *Calamostachys Binneyana*, Schimper. It was shown that the so-called "nodes" at which the sporangiophores arise are not true nodes. There is no secondary xylem at that level, the protoxylem canals are not obliterated, no "gaps" are seen in the cauline bundles, and the medulla is not modified as at the true node. The slender vascular traces supplying the sporangiophores may be arched before entering them. Below the sporangiophore the traces may occasionally be seen lying on either side of the corresponding cauline bundle, often freed from it by maceration. There is con- siderable evidence to show that the sporangiophore trace preserves its identity down to the subjacent true node. The axes, which are commonly described as possessing six bundles in three pairs, are shown to possess only three single bundles. Both three and four bundles are proved by serial sections to characterise different parts of the same cone. There is some evidence that the alternation of the bracts has been brought about by their lateral displace- ment. It was shown to be possible to obtain good series of sections by grinding the blocks containing the material and taking photomicrographs of the successively exposed surfaces.—L. E. Adams: A hypothesis as to the cause of the autumnal epidemic of the common and the lesser shrew. The fact that more corpses of shrews are found in autumn than during the other seasons of the year has been a standing puzzle to naturalists, and no wholly satis- factory explanation has hitherto been suggested. The known agencies of destruction, such as conflicts among themselves, attacks of enemies, scarcity of food, and drought, whilst resulting in many deaths, fail to account for the sudden rise in mortality during the autumn. The author, as the result of observations and investigations carried out during a number of years, is decidedly of the opinion that the autumnal "epidemic," as it is called, is due to nothing more than old age, old age in the case of the common and the lesser shrew being reached in, roughly, thirteen or fourteen months. This conclusion is supported by the fact that all specimens of the common and lesser shrew trapped during and after December in a series of years were found to be immature. This hypothesis would account also for the absence of wounds and other marks of violence in many of the corpses found.

Royal Meteorological Society, February 23.—Mr. H. Mellish, president, in the chair.—Dr. W. Makower, A. J. Makower, and Miss M. White: Investigation of the electrical state of the upper atmosphere made at the Howard Estate Observatory, Glossop.—A. W. Harwood: The results of twenty-five registering balloon ascents made from Manchester on June 2-3 last. These were sent up at intervals of one hour, and some extremely interesting and valuable results were obtained from them.—R. G. K. Lempfert and R. Corless: Line squalls and associated phenomena.

DIARY OF SOCIETIES.

THURSDAY, MARCH 10.

ROYAL SOCIETY, at 4.30.—The Causes of the Absorption of Oxygen by the Lungs (Preliminary Communication): C. Gordon Douglas and Dr. J. S. Haldane, F.R.S.—The Action of Nicotine and other Pyridine Bases upon Muscle: Dr. V. H. Veley, F.R.S., and Dr. A. D. Waller, F.R.S.—Studies on Enzyme Action, XIII: Enzymes of the Emulsin Type: Prof. H. E. Armstrong, F.R.S., and E. Horton.—Preliminary Note on the Origin of the Hydrochloric Acid in the Gastric Tubules: Miss M. P. Fitzgerald.—The Extinction of Sound in a Viscous Atmosphere by Small Obstacles of Cylindrical and Spherical Form: C. J. T. Sewell.—The Ionisation of Various Gases by the β -Rays of Actinium: Dr. R. D. Kleeman.

MATHEMATICAL SOCIETY, at 5.30.—Forms for the Remainder in the Euler-Maclaurin Sum-formula: W. F. Sheppard.—The Scattering of Light by a Large Conducting Sphere: I. W. Nicholson.—The 3-3 Birational Space Transformation: Miss H. P. Hudson.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—Short Circuiting of Large Electric Generators and the Resulting Forces on Armature Windings; The Design of Turbo Field Magnets for A.C. Generators with Special Reference to Large Units at High Speeds: Miles Walker.

ROYAL SOCIETY OF ARTS, at 4.30.—Indian State Forestry: Saint-Hill Eardley-Wilmot.

FRIDAY, MARCH 11.

ROYAL INSTITUTION, at 9.—Ionisation of Gases and Chemical Change: Dr. H. Brereton Baker, F.R.S.

PHYSICAL SOCIETY, at 8.—On Coherers: Dr. W. H. Eccles.—Earth-air Electric Currents: Dr. G. C. Simpson.—An Automatic Toepler Pump designed to Collect the Gas from the Apparatus being Exhausted: Dr. B. D. Steele.

MALACOLOGICAL SOCIETY, at 8.—Pleistocene, Holocene, and Recent Non-marine Mollusca from Mallorca. Marine Shells from Alcudia, Mallorca: Rev. R. Ashington Bullen.—Classification of the Gastropoda: R. J. Lechmere Guppy.—On the Occurrence in England of *Valvata macrostoma*, Steen: A. S. Kennard and A. W. Stelfox.—Description of a New Species of Helicodonta from Spain: G. K. Gude.

ROYAL ASTRONOMICAL SOCIETY, at 5.—On the Determination of Celestial Errors: E. B. H. Wade and H. E. Hurst.—(1) Note on Star Colour Nomenclature; (2) Corrections to Colour-spectrum Discordances: W. S. Franks.—Encke's Comet, 1895-1908: O. Backlund.—(1) Meteoric Fireball of 1910, Feb. 17; (2) Meteoric Fireball of 1910, Feb. 28: W. F. Denning.—Measures of Double Stars made at the Royal Observatory, Edinburgh: Royal Observatory, Edinburgh.—*Probable Papers*: On the Systematic Motions of the Stars derived from the Cross Proper Motions of the Bradley Stars: Prof. F. W. Dyson.—The Envelopes of Comet Morehouse (1908): A. S. Eddington.—Notes on Comet A1910: Rev. A. L. Cortie.

SATURDAY, MARCH 12.

ROYAL INSTITUTION, at 3.—Electric Waves and the Electromagnetic Theory of Light: Sir J. J. Thomson, F.R.S.

MONDAY, MARCH 14.

ROYAL SOCIETY OF ARTS, at 8.—The Art and History of British Lead Work: L. Weaver.

TUESDAY, MARCH 15.

ROYAL INSTITUTION, at 3.—The Emotions and their Expression: Prof. F. W. Mott, F.R.S.

ZOOLOGICAL SOCIETY, at 8.30.—A Contribution to the Skeletal Anatomy of *Chlamydoselachus anguineus*, Garman: T. Goodey.—On the Variation of the Sea-elephants: Prof. Einar Lönnberg.—On the Alimentary Tract of certain Birds, and on the Mesenteric Relations of the Intestinal Loops: F. E. Beddard, F.R.S.

MINERALOGICAL SOCIETY, at 5.30.—A New Form of Petrological Microscope, with Notes on the Illumination of Microscopic Objects: G. W. Grabham.—On Datolite from the Lizard District: W. F. P. McLintock.—A Suggested Modification of Stereographic Projection: Dr. J. W. Evans.—Exhibit of Models illustrating the Space-lattices and Sohncke's Regular Point-systems: Prof. H. L. Bowman.

ROYAL STATISTICAL SOCIETY, at 5.—Notes on the Financial System of the German Empire: Wynnard Hooper.—The Increased Yield per Acre of Wheat in England considered in Relation to the Decreased Acreage: H. D. Vigor.

ILLUMINATING ENGINEERING SOCIETY, at 8.—Discussion on the Measurement of Light and Illumination.

INSTITUTION OF CIVIL ENGINEERS, at 8.—Birmingham Sewage-disposal Works: J. D. Watson.—Salisbury Drainage: W. J. E. Binnie.

WEDNESDAY, MARCH 16.

ROYAL SOCIETY OF ARTS, at 8.—The Foundations of Stained Glass Work: Noel Heaton.

ROYAL MICROSCOPICAL SOCIETY, at 8.—Antipatharians from the Indian Ocean: Miss S. B. M. Summers.—(1) On the Visibility of the Tertiaries of *Coscinodiscus asteromphalus* in a Balsam Mount; (2) Critical Microscopy: E. M. Nelson.

ROYAL METEOROLOGICAL SOCIETY, at 7.30.—Climatic Influences in Egypt and the Sudan: Captain H. G. Lyons, F.R.S.

ENTOMOLOGICAL SOCIETY, at 8.

THURSDAY, MARCH 17.

ROYAL SOCIETY, at 4.30.—*Bakerian Lecture*: The Pressure of Light against the Source: the Recoil from Light: Prof. J. H. Poynting, F.R.S., and Dr. Guy Barlow.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—*Further discussion* (1) Short Circuiting of Large Electric Generators and the Resulting Forces on Armature Windings; (2) The Design of Turbo Field Magnets for A.C. Generators with Special Reference to Large Units at High Speeds: Miles Walker.

INSTITUTION OF MINING AND METALLURGY, at 8.—Annual Meeting.

LINNEAN SOCIETY, at 8.—The Life-history of *Chermes himalayensis*, Stebel on the Spruce, *Picea morinda*, and Silver Fir, *Abies Webbiana*: E. C. Stebbing.—A Contribution toward a Knowledge of the Neotropics: Thysanoptera: R. S. Bagnall.

INSTITUTION OF MECHANICAL ENGINEERS, at 8.—Compounding and Superheating in Horwich Locomotives: G. Hughes.

FRIDAY, MARCH 18.

ROYAL INSTITUTION, at 9.—The Dynamics of a Golf Ball: Sir J. Thomson: F.R.S.

INSTITUTION OF CIVIL ENGINEERS, at 8.—The Construction of Warships: N. Maas.

SATURDAY, MARCH 19.

ROYAL INSTITUTION, at 3.—Electric Waves and the Electromagnetic Theory of Light: Sir J. J. Thomson, F.R.S.

THE LIFE OF LORD KELVIN.

The Life of William Thomson, Baron Kelvin of Largs. By Silvanus P. Thompson. Vol. i., pp. xx+584; vol. ii., pp. xi+585-1297. (London: Macmillan and Co., Ltd., 1910.) Two vols. Price 30s. net.

THE task of the biographer is, in several respects, a very different one from that of the scientific historian. Indeed, it may be affirmed with some shadow of truth that the best biography belongs to the domain of imaginative literature. For to be perfectly successful the biographer must make a hero of his subject; in other words, he must, as an artist, idealise without destroying the features he endeavours to portray. Too often he is a mere ordinary photographer who removes wrinkles and smooths over defects, and thereby produces a picture, recognisable indeed, but of a man in unnatural pose, and ill at ease in holiday garments. Again, the true artist does not crowd his canvas too much, nor does he labour the details of his picture too diligently; we are not tempted to look through our magnifying glasses at particular parts of it, to our loss of the effect of the whole. Finally, he must write from personal knowledge, and with the warmth of personal affection; but he must not allow his feelings to outrun his discretion, or permit his devotion to blind him to the fact that his hero shared the limitations of ordinary humanity. It is just to say that Prof. Thompson passes these tests with a fair measure of success. His biography is well and sympathetically written, it affords a vivid, and, on the whole, a true picture of Lord Kelvin as a student of science, as a university teacher, as an engineer and man of affairs, and as the colleague and friend of a large circle of those devoted to science. If here and there—for example in the account of the latter part of Lord Kelvin's student career and of the proceedings at the Kelvin jubilee—the detail is worked with too microscopic minuteness, the lines are generally bold enough to show the man and his work in fair proportion, and to give the reader with a feeling of contentment with the manner in which the story of a great life has been told and its achievements recounted.

The task of the scientific historian has already been attempted by Larmor, who has framed an estimate of Lord Kelvin's work such as hardly anyone else could have composed at the present time. But that work will not be seen in its true perspective until some interval of time has elapsed; its full effect on the progress of science cannot until then be traced in full in the complicated web of scientific fact and story which so many artists have woven, each interpreting the part of nature's design which lay before his eyes.

The sketch of Prof. James Thomson, Lord Kelvin's father, and of college life in Belfast and Glasgow in the second, third, and fourth decades of the nineteenth century, is somewhat more meagre than it might have been, perhaps; and a little later, when the professor of mathematics appears again, the picture

seems a little out of focus. Tales of his efficiency, and of the respect and admiration with which his students regarded him as a teacher, are still current among the few Glasgow graduates who remember the old college as it was in those days, at the beginning of the last quarter of a century of its existence. But no doubt many of the readers of Prof. Thompson's book, like the present writer, have come to it fresh from the perusal of the charming account of the family life of the Thomsons contained in Miss Agnes King's recently published "Lord Kelvin's Early Home"—the reminiscences of Mrs. King, Lord Kelvin's eldest sister—a narrative which, Prof. Thompson tells us, he has purposely refrained from trenching upon.

Prof. James Thomson's oral examinations are still spoken of as stimulating and instructive, and his example was followed with success in Aberdeen by David Thomson, who went there to be professor of natural philosophy after teaching Dr. Meikleham's classes during the years that preceded William Thomson's return from Cambridge. But the power of effective oral examination, like that of maintaining order without effort, is the result of a certain almost indefinable personal quality which many highly gifted men do not possess. The advent of Dr. James Thomson put an end at once to the pea-shooting and other antics in which the students of mathematics had previously indulged; and his personality impressed itself in other ways on university discipline and the conduct of university affairs, through his influence as a member of the Faculty, which, not the Senatus, was then the administrative governing body. In later days the respect which the students felt for William Thomson's scientific eminence, and the controlling force of his temperament, combined to preserve order in his presence and prevent the most daring from taking liberties. His oral examinations, however, were rather an occasion for digressions, which, though highly interesting and instructive in themselves, were not always such as to recall and elucidate the topics dealt with in the previous lecture.

The old college, Prof. Thompson says, was surrounded with horrible slums, and no doubt its environment was sufficiently wretched. This should not be misunderstood. Things were not always so bad in that part of the city, and at the present time, thanks to the Glasgow City Improvement Trust, the conditions of life in the east end have been greatly improved. In the 'thirties and 'forties, when the Thomsons lived in the residential court of the college, the old order of things was passing away. Bailie Nicol Jarvie no longer lived over his counting-house, and the tobacco lords and other wealthy merchants, grown distrustful of the comforts of the Saltmarket, were migrating from Virginia Street to comfortable villas and self-contained houses in the west end, where in a freer air and more healthful surroundings they lived a not much less frugal life. The birth and development of engineering established factories on the Clyde, and brought labourers and mechanics from all quarters. The lanes of the east end were transformed, from places not very different from those which abut against

some of the colleges of Oxford and Cambridge, to rookeries of the worst description. The University had either to await the amelioration of these surroundings, which came later, or leave its beautiful old quadrangles to seek a new home where no such environment existed. Since its establishment on Gilmorehill, it has found the growth of engineering science react enormously on the study of natural philosophy; and now a great new Natural Philosophy Institute and the James Watt Engineering Laboratories exist together, within hearing of the clang of hammers in the great practical laboratories of the Clyde, with which, by their students and the practical problems which continually arise for solution, they are kept constantly in touch. The opening of this institute and of other new buildings by the Prince of Wales on April 23, 1907, was the last public ceremony at which Lord Kelvin presided as Chancellor of the University. The conferring of honorary degrees on the Prince and Princess, which was only one of the incidents of the ceremony, is mentioned by Prof. Thompson; but the real occasion of the visit, directly connected though it was with Lord Kelvin's own work in the University, has somehow escaped his attention.

A full account is given of Lord Kelvin's undergraduate career at Cambridge, and of the visit to Paris which followed it. By that visit, which he made at the suggestion of his father, and with introductions obtained by him, the young mathematician benefited in many ways. He made the acquaintance of Cauchy, Chasles, Liouville, Sturm, and Regnault, and besides studying French—and the cornopéan—under Parisian teachers, devoted himself to practical physical work under Regnault, who was perhaps the greatest experimentalist of the century. He received no systematic instruction in experimenting—there was then no provision for such instruction, nor for long after was any provided at any university—but he was present to work the air-pump or to hold a tube, or to stir a calorimeter when told to do so, and thus learned something of the technique of physical manipulation. It must be admitted that he never became himself an expert at such work; and his natural impetuosity in later years, when the irons he kept in the fire were almost innumerable, made his presence in the laboratory a source of perturbations which seriously interfered with the systematic progress of research. Thus there was just a shade of truth in the legend—written on the blackboard by a laboratory student when the knighthood after the laying of the 1866 Atlantic cable was announced—“The (k)night cometh when no man can work”!

The story of his election to the chair of natural philosophy in 1846 is told in detail, and it is interesting to read the principal testimonials presented by Thomson, which have been printed from a complete set in the possession of Dr. Hutchison, of Glasgow. There can be no doubt that he had already impressed all the scientific men whom he had met with his extraordinary ability and promise, and all who support his candidature—including MM. Regnault and Liouville, and Hopkins, Fuller, Leslie Ellis, and De Morgan, predict for him a dis-

tinguished future as an investigator. In an appendix to chapter v. (the subject of which is “The Young Professor”) is printed the famous introductory address which was annually brought out to be read at the first meeting of the natural philosophy class for the session, but which was invariably departed from within the first three or four minutes; and laid aside to be taken up again only after the lapse of another year. It was a matter for regret that it was not read through each year—it was read through in 1846, in much less than the allotted time, and Thomson was so disconcerted that he could find nothing to go on with!—for its language is simple and yet dignified, and well fitted to impress the minds of youthful students beginning the study of natural science. In this address he distinguishes between what he calls “mental history” and “mental philosophy,” and between “natural history” and “natural philosophy.” He says that

“What may by the analogy of terms be called *mental history*, that is to say, a combination of personal experience and a knowledge of men and of manners, with the study of politics and history, leads us to reason upon the abstract properties of mind, and to investigate that system of general laws on which *mental philosophy* is founded. So in the study of external nature, the first stage is the description and classification of facts observed with reference to the various kinds of matter of which the properties are to be investigated; and this is the legitimate work of *Natural History*. The establishment of general law in any province of the material world, by induction from the facts collected in natural history, may with like propriety be called *Natural Philosophy*.”

Thus the observations, and their comparison and classification, which led to Kepler's laws, belong to the “natural history” of celestial mechanics. Newton's deductions from Kepler's laws, and the theory of universal gravitation, which accounts for all the motions of the planets, belong to the “natural philosophy” of the subject. The fundamental subject of natural philosophy is said to be dynamics, or the science of force, and it is interesting to find the importance of this foundation insisted upon for all the principal divisions of physics. Referring to three of these—heat, electricity and magnetism, he says:—

“Our knowledge of these branches of the science is not so far advanced as to enable us to reduce all the various phenomena to a few simple laws from which as in mechanics, by means of mathematical reasoning every particular result may be obtained; but observation and experiment are the principal means by which our knowledge in this department may be enlarged. Hence what is called the experimental or physical course includes these three subjects; while the more perfect sciences of mechanics [here he means “dynamics”; “mechanics” he always defined as “the science of machines”] and optics, being really mathematical subjects, form a distinct division of the study prescribed by the University for the complete course of Natural Philosophy.”

Thomson does not seem to have dwelt on the deductive processes of mathematical physics in his address, though these are quite as important as induction with which they must be combined. The deductive process by which Adams and Leverrier

out the place of the planet Neptune from the perturbations of Uranus, gave a result which, when found to agree with observation, was generally regarded as affording a much more forcible proof of the truth of the gravitational theory than all the induction which preceded it, and the same thing may be said of results in other departments of physics, which illustrate the *predictive* value of a true theory. A reference to Adams and Leverrier, and the discovery of Neptune, was made in the address, but after 1862 it was omitted by the advice of Prof. Tait, who thought that the subject of Neptune had been "ridden to death."

The provinces of heat, electricity and magnetism, which are referred to in the introductory address as lying in great measure outside the scope of dynamics, it was Thomson's destiny to bring under the sway of the science of forces. He is already, when in Paris, meditating on the results set forth in Gauss's great memoir on attracting and repelling forces varying inversely as the square of the distance, and noticing how the general theorems there given lead to conclusions which were afterwards expressed in the language of the theory of energy. The letter (quoted on p. 130) is interesting in this connection and in some others.

"April 8, 1845. To-day, in the laboratory (of Physique at the Coll. de France, M. Regnault, Prof.), I got the idea which gives the mechanical effect necessary to produce any given amount of free electricity, on a conducting or non-conducting body. If m is any electrical element, v the potential of the whole system upon it, the mechanical effect necessary to produce the distribution is $\sum mv$ Also the theorem of Gauss that $\sum mv$ is a minim. when v is const., shows how the double int^l which occurs when we wish to express the action directly, may be transformed into the diff.-co. of a simple int^l taken with reference to the distance between the two spheres. . . . This has confirmed my resolution to commence experimental researches, if ever I make any, with an investigation of the absolute force of static electricity. As yet each experimenter has only compared intensities by the dev^{ns} of their electrometer."

Here we have the train of ideas in progress which, no doubt, to some of the series of papers on the mathematical theory of electricity which were published later in the *Cambridge and Dublin Mathematical Journal*. But what is still more particularly to be remarked is the determination to measure forces in absolute units. In the discussions of Lord Kelvin's work which have appeared in print, hardly sufficient importance has been attached to the part which Thomson played in the working-out of the scheme of absolute measurements the beginnings of which were made by W. Weber and Gauss. Perhaps, as he confessed later in one of his addresses, he never succeeded in getting the capacities of the leyden jars in his laboratory expressed exactly in absolute units, but it became possible to obtain a fair estimate of these capacities, and to measure, also in absolute units, by means of the beautiful electrometers which he afterwards made, the potentials to which the jars were charged, and therefore to say approximately, in ergs,

how much energy was stored up in a particular jar when charged to the measured potential. Each experimenter, he says, expressed his results in terms of the deflections of his own electrometer: not merely was that the case, but currents were measured by each experimenter in divisions on his own galvanometer, and the insulation resistance of a cable at one time could only be compared with its value at another time by using the same instruments as before and reproducing exactly the former conditions. All this had to be swept away and an absolute system substituted when Atlantic cables began to be laid; but an enormous amount of exceedingly valuable work, both theoretical and experimental, had to be done ere a proper system could be elaborated. No small amount of this was accomplished by Thomson and his volunteer laboratory corps at Glasgow, in the "coal hole at the old college," as some members of that corps have since described the famous "first laboratory for students." Then the toil which the members of the British Association Committee undertook in working out, perfecting, and realising the system of units! It was work which did not attract public attention or strike the public fancy; and yet hardly anything else has done more to render possible practical applications of electricity in all their modern ramifications.

In the early 'fifties came the papers on the theory of heat. The account of Carnot's theory of the motive power of heat, with its determination of Carnot's function from Regnault's experiments on steam, valuable as it was, seems to have led Thomson's thoughts into a kind of groove, from which, when Joule's proof that heat and work were equivalent was published, he had some difficulty in escaping, and which involved him in considerable perplexity. It is, as Prof. Thompson says, entirely to the credit of Clausius that he saw clearly at once the full force of Joule's discovery, and accepted implicitly the first law of thermodynamics to which that discovery pointed. After that the necessary modification of Carnot's theory followed immediately, and Carnot's notion of a cycle of operations enabled the whole of the immediate consequences of the true dynamical theory to be worked out. A little later, but independently, Thomson also arrived at the true theory, and by an "axiom," or rather postulate, very differently expressed from that employed by Clausius, but on the whole equivalent, showed that the efficiency of all ideal thermodynamic engines, no matter what their working substances were composed of, had the same value. This in Thomson's hands led afterwards to his definition of absolute temperature, a conception which Prof. Tait used to insist, in the pages of *NATURE* and elsewhere, was of the most enormous importance, and ought to be set forth at the outset in every treatise on the subject.

Thomson's great paper, followed up as it was by developments and applications of the theory in his later writings, was destined to exert a profound influence on the study of thermodynamics both in this country and abroad. This result was in part due to the peculiarities of his treatment of the subject, which were characteristic of his practical genius.

The object of the memoir is first clearly announced, then the process and its results are unfolded, with a reference at every principal step to the physical meaning of the operation performed and the result obtained; and in every part the process adopted is preceded by a carefully worded statement of the assumptions made, and the presuppositions involved. Clausius, on the other hand, and with him almost every Continental writer, begins by referring to an undefined substance called a "perfect gas," and by means of that substance absolute temperature is defined as R/pv , where R is a constant and p and v are respectively the pressure and volume of a given mass of the gas. Thomson obtained his scale of temperature by means of an ideal engine; and then came the comparison of his scale with that of the air thermometer, by means of his porous plug experiment, which he carried out in collaboration with Joule, in the famous series of experiments on the thermal effects of fluids in motion. This experiment falls at once into clear relation to the whole theory in Thomson's sequence of ideas; this is hardly the case in the other mode of treating the subject.

The earlier papers on heat were all communicated to the Royal Society of Edinburgh, of which Thomson became a fellow in 1847. Of this society he was Keith medallist in 1864, and one of the chief grounds for the presentation of the medal was the discovery of the theorem of minimum energy of a system of connected particles, started by impulses applied at specified points and subject to the condition that the velocities of these points have specified values. This theorem is stated by Prof. Thompson on p. 1141, with rather less than sufficient caution; for if the condition be that the *impulses* applied at the specified points are also specified the motion is one of maximum energy. The far-reaching scope of this theorem is now much better understood than it used to be; for example, by analogy, certain theorems of electricity may be regarded as particular cases of it. The whole subject of these general dynamical theorems has been discussed by Lord Rayleigh in his "Theory of Sound."

The appointment of Tait to the chair of natural philosophy in Edinburgh led to the literary partnership which had as its result the publication in 1867 of the first volume of the "Treatise on Natural Philosophy," and in 1873 of the companion volume, "The Elements of Natural Philosophy." It is matter of keen regret that the second volume at least of the treatise was not forthcoming. For continually in his lectures in 1874, and for some years later, Thomson referred to the discussion of properties of matter which would be contained in that volume, and references to it are frequent in vol. i. If that chapter had been given to the world the treatises on electricity, sound, and hydrodynamics, which we owe to Maxwell, Lord Rayleigh, and Lamb, might well console us for the abandonment of the original scheme. But, as it is, all the old Glasgow students of natural philosophy, who have kept up the study of the subject, will ever regret the loss of the promised chapter, of which they obtained now and then glimpses, when Thomson referred, for example, to the difficulties of the elastic solid theory of the æther, and showed that

similar difficulties arose when we attempted to explain the properties of cobblers' wax!

A good idea of Tait's breezy and energetic style of work will be obtained from the letters printed at p. 453, and elsewhere. He was a man of the most kindly feeling and disposition, though the native force of his character and intellect made him a formidable opponent and a severe critic and controversialist. His famous lecture on force will never be forgotten by those who heard it in the Kibble Palace, in Glasgow, in 1876; only a faint idea of it can be obtained by reading his "Recent Advances in Physical Science." He was orderly and methodical; his statements, whether oral or written, were brief and precise, and his lectures were commended by all his students for their unfailing experimental illustrations and the clearness of their expositions.

Thomson could also be clear and precise, nobody more so; but in his popular discourses he was always so preoccupied, and every thought so inevitably suggested new and interesting relations of things, that all his hearers, except a very few, quickly gave up the attempt to follow his lecture, and settled down to listen in admiration and amazement. The writer will never forget the discourse on "Isoperimetrical Problems" which Lord Kelvin delivered at the Royal Institution in May, 1893. The half-humorous picture of the wounded Horatius Cocles limping after the plough, and drawing his furrow so as to get the greatest possible area of land within the given length of boundary, brought the problem home to even the most unmathematical dweller in Mayfair who was present; but when the lecturer went on to make Horatius take account at every step of the quality of the soil, so as to place the maximum value of corn land within his boundary, wonder melted into sympathy for the crippled warrior confronted with such a terrible task! It is well known that the Friday evening discourses must begin at nine o'clock and terminate precisely at ten; but this law, which no one else dared to break, Lord Kelvin disregarded, for when ten o'clock came he had just got into his subject, and he went on—with apologies, of course—until nearly eleven! Such were his fire and enthusiasm; and to the few who remained to the end the *tour de force* was amazing. This would never have happened with Tait; the whole matter would have been thought out from beginning to end; all ideas that might have led him from his straight path would have been ruthlessly put aside, and a model of polished and clear exposition presented. As a rule, Thomson's sentences, both written and spoken, were too heavily loaded with saving clauses; as if he considered himself too absolutely committed to a conditional statement, if its limitations were not all given with it in one word-formula.

It is little wonder in some ways that the literary partnership broke down. But the book was, as Prof. Thompson has called it, emphatically an epoch-making one. It called for and brought about a return to Newton in dynamical method; and it pointed out how the neglected *scholium* on Newton's third law contained in substance the theory of energy. Other text-books are more popular; even the "Elements"—

consisting as it did in many places of the large-type statements of the treatise, without the small-type mathematical demonstrations—was too strong meat for the babes of the Glasgow class. The muttered groans of the students, when on Friday Thomson would first ask them to read twenty or thirty pages of the book before Monday, and then turn to McFarlane and tell him to see that questions were set on the part prescribed in the forthcoming Monday morning examination paper, never reached his ear, and with a bland smile, as if he had just prescribed a novel for the week-end, he used to turn to his oral examination and his lecture.

With regard to the somewhat strong remarks, which we find quoted on p. 445, as to the absurdity of causing Thomson to teach elementary physics, it is right to say that in 1846, when he sought and obtained the chair, the plain everyday duty of the professor of natural philosophy was to teach the natural philosophy class, and that, so far as Thomson was concerned, his time, energy, and original power were far from wasted in meeting from day to day his band of students, most of them eager to learn, and many of them willing to help in his researches. There is no doubt whatever that the attempt to teach them gave him inspiration, and from them came, as another important reward, his laboratory corps, who helped him so much. Witness the tribute to the divinity and other students in the Bangor address. Moreover, it does not seem to be generally known that from the early 'seventies onwards Thomson met the ordinary class only twice, and the higher class only once, a week. He would most certainly have been himself the strongest objector to any arrangement that would have cut him off altogether from his ordinary students. The reflection on the University is undeserved.

Prof. Thompson's second volume begins with 1871, in which year Thomson was president of the British Association at its meeting in Edinburgh. During the following fifteen years or so he was at the height of his activity. His Atlantic cable-laying expeditions were over in 1869, and he had purchased the *Lalla Rookh*, and begun the series of yachting excursions and hydromechanical and other experiments at sea which resulted in the compass and sounding machine. A year or two later some further cable-work was undertaken, which occasioned an eventful visit to Madeira; and then came the introduction into navigation of the fully corrected compass and the sounder, which are now in one form or another on board every well-found and properly equipped sea-going vessel. In the 'eighties he delivered the Baltimore lectures, and invented the various standard electrical instruments for exact laboratory and workshop measurements. Afterwards, in the 'nineties, came the egerage, the presidency of the Royal Society, and the ever-to-be-forgotten jubilee celebration in 1896.

Of Lord Kelvin's cable work, both theoretical and practical, extending from 1857 to 1874, and of his any other practical activities, Prof. Thompson's book contains an admirable account. It is written in such a way that anyone, however non-mathematical or non-physical, can read it with interest and enjoy-

ment. No such person can lay down the second volume without a feeling of amazement that so much achievement in high regions of scientific discovery and invention could be crowded into one life, even though that extended far beyond the Psalmist's three score years and ten. Indeed, the book may do much good by telling the public at large how much it is indebted for its safety in travelling, for telegraphic communication from continent to continent and between the old world and the new, and for many other benefits (to say nothing of the advancement of natural knowledge), to patient investigation carried on by one man and his corps of willing students and assistants.

There are a few corrections here and there that we should like to see made in a new edition, but these are not of any great consequence, and need not be here enumerated. We have come to the end of the space allotted to this review, and only a few points here and there have been touched upon. The thronging memories of the past suggest innumerable topics on which we might dwell. All around are memorials of the great man who has passed away and the work he carried through. But it is better to forbear, and in a last word to commend Prof. Thompson's book to all who care to know something of the life and the victories of a leader of the armies of peace.

A. GRAY.

DYNAMIC ELECTRICITY.

Electricity. By H. M. Hobart. Pp. xix+207. (London: Constable and Co., Ltd., 1909.) Price 6s. net.

IN this book the author attempts to impart to the reader a fundamental knowledge of dynamic electricity without using mathematics, or rather without giving mathematical proofs of his statements. He evidently believes in the possibility of such study, for in the preface he says that

"Without any accompanying study of other text-books, almost anyone who is in earnest can make good progress in acquiring a fundamental knowledge of the subject of electricity, by a careful study of the present treatise."

Now this is rather an ambitious statement, but if the author had followed the orthodox method of using mathematics in elucidation of experiment he might have succeeded. He has, however, deliberately discarded the use of the most efficient tool we have in the interpretation of experimental results, and thus the task of the reader is made more difficult, and not more easy, as he hoped to make it. The author cannot do entirely without mathematics, or at least without expressing certain relations by mathematical formulæ, but he gives these without showing how they are obtained, merely as statements without proof. Here are a few examples: on p. 59 we are told that a circular conductor 1 cm. long, and carrying 10 amperes, acts on a unit pole in the centre of the circle with a force of 1 dyne. No proof is given for this statement; yet, starting from this, the author develops, also without mathematical proof, the law that the magnetic field round an infinite straight con-

ductor varies inversely as the distance from the conductor. On p. 83, merely as a footnote, we get a simplified version of Minchin's formula for the total flux through a coil of circular cross-section, and on p. 85 Perry's formula for the flux through a coil of rectangular cross-section. On p. 87 we find the well-known formula for the induction in the centre of a long solenoid, but in none of these cases is a proof given.

This tendency to do without mathematical reasoning is surely futile; a reader who does not know even the small amount of mathematics which suffices for the elementary study of electricity had better leave the subject alone; and the reader who has the required mathematical knowledge is not helped by finding the most simple relations set forth in long tables and perfectly obvious diagrams. Yet the book is interesting to the man who knows the subject. He will find many things, which are treated in all text-books in the orthodox way, presented in a different manner, and although the treatment is sometimes rather verbose, it is at any rate original. As regards nomenclature, the originality is perhaps carried a little too far. That the term "kelvin" is used to denote the unit ordinarily called the kilowatt-hour might be passed over as permissible, since some other authors have adopted the same term, though it is by no means generally accepted; but there is no justification for introducing the term "siemens" for the watt-hour. This unit is hardly ever used, and to coin a special term for it is quite unnecessary. The terms "continuous electricity" and "alternating electricity" are also unusual, whilst the abbreviation "ats" for ampere-turns is not very happily chosen.

The first six chapters, dealing with the specific resistance of conductors, the conception of current, voltage, energy, power, and explaining Ohm's law, are very elementary. The definition of the unit of energy, taken as the kilowatt-hour, is unusual. According to the author's nomenclature, the "kelvin" is that amount of energy which will raise the temperature of a ton of water by 0.86°C . This is surely a round-about way for a book on electricity, especially as the conception of the mechanical equivalent of heat is not used to connect the "kelvin" with the "joule," but the relation between the two units is simply stated in a table.

The following chapters deal with the magnetic field, the E.M.F. generated in moving conductors, alternating currents, inductance, the magnetic circuit, and insulating materials. The passage dealing with the relation between time and current in a circuit to which an E.M.F. is suddenly applied is an object-lesson of the futility of attempting to treat such a subject without mathematical basis. It cannot be done; and thus we find Helmholtz's formula suddenly introduced without any proof, and then worked out at great length algebraically for a special case. Then we get to the time constant and more numerical calculations, with the usual complement of tables and curves. The best chapter in the whole book is that on insulating materials. Here we get on to the solid ground of experimental evidence. Tables and curves are given

for the disruptive strength of a great variety of insulating materials, the influence of temperature is discussed, as are also the methods of testing for disruptive strength and the thickness of slot insulation found necessary from practical experience. The specialist who has to design high-pressure machinery will find this part of the book very useful.

GISBERT KAPP.

AN ARTIST-ORNITHOLOGIST IN EGYPT.

Egyptian Birds, for the Most Part seen in the Nile Valley. By Charles Whympers. Pp. x+221; with 51 coloured plates. (London: A. and C. Black, 1909.) Price 20s.

WE have nothing but praise for Mr. Whympers' drawings. Being more ⁱⁿ the nature of landscapes with birds in the foreground than figures of birds with a suitable background, they naturally gain from an artistic standpoint, and this has not detracted from their value as guides towards identification. Many of the drawings are, indeed, most pleasing pictures, and convey a delightful impression of the surroundings amongst which the visitor to Egypt may expect to see the birds depicted. On the whole, Mr. Whympers has not suffered greatly at the hands of the block-maker, though we may remark generally that the colouring of the plates is more pleasing by artificial light than by daylight, and we imagine that the green legs and feet of the griffon vulture, the purple hues of the chats, and such like inaccuracies in colouring are due to the engraver's or printer's art rather than to the artist's.

Whether the author has been wise in his choice of "types" of Egyptian birds—only some fifty or sixty species in all are figured and described—is perhaps a matter for argument, but in a book which aims at teaching the traveller in Egypt "something of the birds he sees," it seems a waste of opportunity to devote plates and descriptions, amongst so few, to such birds as the kingfisher, house-sparrow, heron, snipe, and lapwing, which every Englishman who takes the smallest interest in birds must know; while the inclusion of the shoebill, which has never occurred in Egypt, because it is a favourite at the Giza Zoological Gardens, is really absurd—one might as well include the giraffe in an account of the mammals of England! The use of the book as an aid to identification is thus very small, for it will help the average Englishman to identify barely forty birds which he does not already know, and the volume is a large one for so small a gain in knowledge.

Turning now to the letterpress, the author disarms minute criticism by his statement that the book is not intended for the ornithologist, but he implies that its purpose is, in some measure at all events, educative, so that we may fairly point out some inaccuracies, for we cannot commend the author's ornithology in the same spirit as we can his art. As an example, we may direct attention to the description of the crested lark, in which not a word is said of there being a number of well-marked geographical races of this bird peculiar to different localities in Egypt—obviously a very interesting point which, had it been explained,

would have caused Mr. Whympers's readers to look carefully at the crested larks they saw instead of passing them over as "nearly the commonest birds." Which form is represented in the plate it is difficult to say, but certainly neither the almost black *Galerita cristata nigricans* of the Delta nor the pale, sandy-coloured *G. c. altirostris* found to the south of Cairo could be recognised from the drawing.

Again, on p. 76 the extraordinary statement is made that the red-spotted bluethroat has never occurred on migration in Germany, and that it flies without a halt from Africa to Scandinavia. Because many of the migrants which occur in winter in Egypt are of the same species as those which occur in north-western Europe in summer, it is unreasonable, we think, to suppose that they are the same individuals. The further statement that the bird is but an accidental visitor to Great Britain, and hardly worthy of a place on the list of our birds, should also be corrected, since it has been proved during the last ten years, at all events, to be a regular annual bird of passage in the autumn. We have no wish to criticise unduly, but we think it behoves an author to be even more careful of his facts in a popular book of this kind than in a book intended for readers who would not be so likely to accept his statements unchecked.

The ornithologist reading Mr. Whympers's pages may cull a few observations of interest, such as a note here and there on the winter habits of some of the migrants. The list of birds at the end of the volume is so far from being complete that we cannot think that it has been revised by Mr. M. J. Nicoll, who is credited with having assisted the author in making it "as complete as possible."

THE EVOLUTION OF AGRICULTURE.

Die Entstehung der Pflugkultur. By Dr. Ed. Hahn. Pp. viii+192. (Heidelberg: C. Winter, 1909.) Price 3.60 marks.

IN the study of culture-origins there seem to be three working hypotheses. According to one, institutions and material inventions were, so to speak, "forced" upon man by the various exigencies of his life. "Necessity is the mother of invention." According to another, religion, or rather magic, initiated such steps in progress. A third combines these; a step when made was enabled to persist and be improved by the influence of religion.

But each of these hypotheses, as others, takes into account the psychological factors. How did the idea of an invention occur? Is it the first step that counts; given the first step, for instance, in the evolution of the bow, and the rest is easy. How, then, did man hit upon the first step? Among the conditions to be posited are "play" and accident. There is a good deal to be done in the investigation of the first steps of what may be called the primary inventions.

Dr. Eduard Hahn has written many volumes and papers on economic history and culture-origins. He is a suggestive writer, and is always ready with

a comparison between modern and primitive "diapasons," in Lamprecht's phrase for social atmospheres. The present volume is more or less supplementary, as an answer to criticisms of his theory of the origins of agriculture.

This theory is the magical-religious. It has been severely criticised, and we must admit that in this re-statement and defence Dr. Hahn fails to convince. His method is almost as elliptic as Prof. Adolf Bastian's. A closely reasoned argument confined to one detail, for instance, the relation of the "Moon Goddess" to the evolution of husbandry, and employing careful analogies when a step is taken from one people to another, or from one culture-stage to another, would have had better results. But he seems to rely on the cumulative effect of data which are of the most diverse nature and value. Thus we have in unequal yoke a piece of folklore from Hesiod or Macrobius, with a savage practice of the Australian Arunta and a German peasant custom. But his theory is too fanciful to be able to rely on such data.

The points of the theory are mainly these: the basis of primitive subsistence was vegetable, not animal. The three-stage hypothesis of hunting, herdsman-ship, and husbandry is traversed. The primitive *Hackbau* is distinguished from agriculture proper, *Pflugbau*. Woman was the chief agent in primitive economics, as the "gardener" with her digging-stick. Thus far the theory is sound. But it proceeds to urge the "religious" origin of the domestication of animals, of the use of milk, of the wagon and its wheels, and of the plough, all in connection with the cult of the Moon. Much is made of the sporadic indications of the connection of phallism with the "idea" of ploughing.

Dr. Hahn's sketch of the primitive symbiosis of Headman, Medicine-man, and Woman is good reading. The Medicine-man protects the primitive "crop" from ghostly enemies, and secures for it ghostly strength. The Headman organises material defence, and, when free, the ordinary male hunts. But primitive society was probably not quite like that; in particular it is easy to exaggerate the influence of "religion."

A. E. CRAWLEY.

OUR BOOK SHELF.

A Manual of Locomotive Engineering. By W. F. Pettigrew. Third edition, revised. Pp. xv+356. (London: C. Griffin and Co., Ltd., 1909.) Price 21s.

WE had pleasure in noticing the first edition of this book some ten years ago, when a favourable opinion was expressed as to its value as an educational means of assisting students of locomotive engineering in its many phases.

The author claims to have brought the work thoroughly up to date, and, considering the tremendous advances made in this branch of engineering during the last ten or more years, we naturally expect some evidence of really modern practice in the third edition. It is very disappointing to find this is not the case. Plate i. illustrates what the author describes as "the new outside cylinder express engines designed by Mr. W. Adams," &c. As Mr. Adams joined the majority

some years ago, and as the engines referred to were designed many years before then, it is absurd to illustrate them as modern practice when the magnificent creations of Mr. Wilson Worsdell on the North-Eastern and those of Mr. McIntosh on the Caledonian are available.

The compounding of locomotives has also been very seriously considered by many engineers, particularly during the last ten or twelve years. The Webb and Worsdell systems being more or less obsolete, one naturally expected to find the Smith system with three cylinders, which originated on the North-Eastern, engine No. 1619 being the prototype, described and illustrated by one of the recent Midland compounds. Another type of compound represented by the four-cylinder engines on the North-Eastern is conspicuous by its absence.

Of the subject of superheat, which is now being seriously considered by most locomotive engineers, we find no reference in this volume. This is surely a serious omission when there are locomotives running on certain railways in this country fitted with the Schmidt system, a system which claims many economies in working when compared with the heavy boiler expenses involved when working with the high pressures necessary with the compound engine.

Although we have considered it necessary to point out that the author's claim of having brought the third edition of this book up to date has more or less failed, it should be clearly understood that its contents are of a valuable nature, and budding locomotive engineers should obtain a copy without delay. It is certainly one of the best books of its kind. The illustrations are good and the general style excellent.

Matter, Spirit, and the Cosmos. Some Suggestions towards a Better Understanding of the Whence and Why of their Existence. By H. Stanley Redgrove. Pp. 124. (London: W. Rider and Son, Ltd., 1910.) Price 2s. 6d. net.

MR. REDGROVE'S theory of matter is that it possesses only a hypothetical reality; we assume its existence only because otherwise the harmony of our individual worlds would be unintelligible. Spirit, he seems to maintain, we know by direct intuition of ourselves—a proposition of great dubiety, if we take spirit in the sense of real substance. But, granting the one a certain, the other a hypothetical objectivity, the objective relation of the two must be determined. Mr. Redgrove holds that God is the ultimate cause of both, spirit the mediate cause of matter. Yet the effect must be regarded as quite distinct and discrete from the cause. It would seem to follow that for God spirit is something analogous to what matter is to us; but this inference is not drawn. Moreover, no reason is given for the ontological subordination of matter to spirit, except the epistemological distinction noticed above; and it might equally be held to prove the ontological subordination of all other spirits to one's own. Mr. Redgrove, indeed, tentatively holds that in telepathy we have direct "sense" of other spirits; but this perception is "symbolic" as well as direct, which means, one must suppose, that it is not truly immediate. The author believes in the immortality of self-conscious beings; but as he also believes that self-consciousness arises out of protoplasmic consciousness by the ordinary processes of the universe, it is not evident why he should assume the impossibility of a relapse into that state. Though these and other difficulties will be met, the book is well worth reading. Mr. Redgrove writes with precision and force, and his discussion is always interesting.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. No notice is taken of anonymous communications.]

The Colour of Water.

I AM reminded by Lord Rayleigh's lecture on this subject of the splendid light-blue colour presented by the tanks of water in which some of the water companies allow the sedimentation to take place of "hard water" which has been treated by Clark's process. I am thinking of those near Caterham and of those at Plumstead. The tanks—to the best of my recollection—are about 20 feet by 40 feet in area and 15 feet deep. The water in the tanks has become perfectly (or nearly) clear, whilst the sides and bottom of the tanks are made brilliantly white by the deposit of calcium carbonate. The intense blue colour is seen at (practically) any angle of vision, and on a sunless, overcast day as vividly as in sunshine. It would be important to ascertain whether the blue colour thus seen is entirely due to the self-colour of the water or whether the phenomenon is in any way due to the minutest white particles of calcium carbonate which are still floating in the apparently clear water, and are acting as do the particles of a blue vapour-cloud. I suppose that it would be an easy thing for a physicist to determine this by the use of a polariscope at the side of the tank.

Also the introduction of black tarpaulin into the tank so as to prevent the reflection of light from the bottom and sides would show whether any amount of blue colour was still exhibited by the water, such colour being then necessarily due to the reflection of light from suspended particles, and not from the sides or bottom. A more satisfactory method would be to draw off (without disturbing the sediment) the blue-looking water into an adjacent tank previously lined with dead-black.

One observation on the colour of water I may venture to record. In a very large porcelain (so-called) bath in a hotel bath-room, where strong sunlight was admitted by a window some 10 feet above the bath, the walls of the room being colourless, I noticed that when the bath was filled to a depth of 20 inches the water had a distinctly blue colour. The porcelain, whilst pure white above, yet *beneath* the water had a distinctly blue appearance, and the intensity of the colour varied with the movement of the water in waves or ripples. The colour was blue rather than greenish-blue, and this I attributed to the pure white of the porcelain as contrasted with the yellowish tint of enamel. The water in question was that supplied in the Hotel Ritz, in Paris (I think that of the Vanne).

E. RAY LANKESTER.

The Stability of an Aëroplane.

I HAVE been much interested in reading Prof. Bryan's statement on the subject of the stability of an aëroplane, but I cannot agree with him in thinking that the solution of the problem is to come from the mathematical side. I should be the last to decry the use of mathematics in such a case, but if the final result is to be absolutely trustworthy, there must be no doubtful assumptions made during the process.

It does not appear, from the article written by Prof. Bryan, whether he has taken the viscosity of the air into account, but I presume that he has done so. Perhaps, also, his solutions are only meant to apply to the case of an aëroplane flying in a dead calm. The practical difficulty with a flying machine is the natural wind, and if flying machines are to be of any real use they must be able to maintain their stability in ordinary conditions of weather. Now it is obvious that when a flying machine has once left the ground it is quite immaterial to the stability, provided the air motion is perfectly uniform and steady, whether the velocity of the wind be one mile or one hundred miles per hour, since it is only the relative motion of the machine and the air with which we are concerned; but, as a matter of fact, a wind of from ten to twenty miles an hour is fatal to almost every aëroplane, and the

reason is not far to seek. The air motion known as wind is not even approximately steady and uniform until at least a height of 1000 feet is reached, and on some days there is no uniformity about it until much greater heights are attained. The supposition made, therefore, that the motion is uniform is incorrect, and if this assumption has been made by Prof. Bryan it limits the use of his equations to times of perfect calm.

He has probably also assumed that the flying machine, or at least the separate parts of it, may be treated as a rigid body. The small gliders made of thin mica, and described by Mr. Lanchester, may, no doubt, be treated as rigid, but cloth or canvas forms an important part of an aeroplane, and however tightly it may be stretched it certainly is not equivalent to a rigid sheet, but must yield under varying pressure.

My practical experience on this subject is with kites, and although there are fundamental differences between a kite and a flying machine, there are many points of resemblance, and it is probable that if the question of the stability of a kite could be completely elucidated, that of the stability of an aeroplane would follow. Almost any kite will fly in a steady wind of moderate velocity, but, so far as I know, there is no kite that will remain stable when the wind increases beyond a certain value. The limit with the kites used here is about forty-five to fifty miles an hour at a height of 1500 feet. The question is, Why do they become unstable? There are, perhaps, three reasons. The flying of a kite depends on gravity, for a weightless kite could not fly, as there would be no directive force. As the wind pressures increase, the necessary relationship between the magnitudes of the pressures and the weight is lost, and the kite becomes unstable. A cure, perhaps, lies in increasing the dead weight. Secondly, the stresses produced by the strong wind very likely deform the kite. It is not possible to meet this by increased strength, for increased strength means stronger, and therefore heavier, materials, and hence, unlike a dead weight at the centre of gravity, a greater moment of inertia, which, as I have long known from practical experience, and Mr. Lanchester has shown from the theoretical side, is inimical to stability. Thirdly, it may be that there is a certain critical velocity, like that of water in a pipe, beyond which the motion over the edges of the sails becomes turbulent, and the form of the stream lines suddenly changes.

These points can best be cleared up by extensive experimental work, and I much regret that no such work is being done.

W. H. DINES.

Pyrtton Hill.

It was difficult to prevent my article from running to ten times its present length, and a similar difficulty occurs in this letter. I can only state that the more I have examined the problem of stability the more I have been brought to conclusions exactly the opposite to those expressed in Mr. Dines's letter. My original view was to limit the mathematical investigation to the formation of the biquadratics and their discriminants, leaving their coefficients to be determined by experiment. In several popular articles I have advocated such experiments. Further experience has shown that there was little prospect of any conclusions of a practical character being obtained without a considerable further development of the problem from the mathematical side.

Moreover, experience has led me to believe that the English practical man is sometimes right when he says that if you cannot get a complete solution of a problem you ought to try to obtain the nearest approach to it that you can, and, further, that an admittedly approximate solution is often more useful than a more complicated exact one. In the present case the methods are perfectly general, and while it would have been futile to start, in the first instance, by making the problem too complicated, there is little difficulty in introducing any necessary modifications subsequently.

In regard to the assumption of uniform relative velocity, surely Mr. Dines is confusing the issues between stability and something else. The very notion of *stability* implies the existence of a state of equilibrium or of steady motion. The behaviour of an aeroplane or kite in a turbulent

atmosphere is a problem, not of stability, but of forced oscillations. The effect of these oscillations is to modify the motion of the kite; but it is necessary in the theory of forced oscillations to assume as a standard of comparison the state of equilibrium or steady motion which would exist if the disturbing forces were absent, and the character of the forced oscillations will depend vitally upon whether this state of equilibrium is stable or unstable. The first thing is to investigate the free oscillations, but there is nothing to prevent the investigation extending to forced oscillations as well. It is only a question of time and opportunity. Meanwhile, aviators are performing record flights on aeroplanes which do not satisfy the conditions of stability, and Mr. Dines's turbulent air currents are getting blamed for much that is not their fault. No solution of the problem can be final which does not completely separate the effects of free and forced oscillations. I do not see how this can be done by purely experimental methods of investigation, and surely the questions which Mr. Dines raises in connection with the behaviour of kites refer to this very point. He has, in fact, stated another problem for the mathematician.

Again, like Mr. Dines, I was at first of opinion that it might be possible to establish a simple connection between the stability of an aeroplane and that of a kite, and I suggested this problem to Mr. Harper. The investigation turned out to be more complicated and less likely to lead to any practical conclusions than was originally anticipated. With so many other problems on hand, it appeared desirable to give this one up for the present. I do not think Mr. Dines will find it possible to obtain an experimental solution. If he can, a great deal of trouble will be saved; but so many variables enter into the problem that it appears to me necessary to start with some idea as to what the connection is likely to be, i.e. with some kind of a mathematical theory as a starting point.

When Newton published his "Principia" it would have been an easy matter for a forerunner of Mr. Dines to raise objections to this attempt to solve problems relating to moving bodies by applications of the laws of motion on the ground that the motions must largely depend on air resistance, friction, the earth's rotation, and other causes, and that a solution which did not take all these effects simultaneously into account could be of no practical value. Similarly, it might have been objected that the solution of the problem of stability of ships could not be approached by means of the theory of the metacentre on the ground that it failed to take account of wave motion, the velocity of the ship, the effects of the wind, and such resistances as viscosity. I venture to suggest that if the above problems had been attacked by purely experimental methods alone, we might still have been in the dark as to their solutions.

In my article I alluded to difficulties caused by "want of opportunity," but out of fairness reference ought to have been made to the similar difficulties referred to in Mr. Lanchester's book. Had his investigations been published when they were made, a large amount of work might now have been accomplished which is still undone.

It is only fair also to add that since the appearance of the note I have had some correspondence with the editor of the *Aeronautical Journal*, and I hope he will succeed in maintaining the same high standard in its published papers of a mathematical character as in its illustrated articles on general aeronautics.

G. H. BRYAN.

Colour-Blindness.

IN the issue of NATURE of January 27 there is a discussion of colour-blindness, with particular reference to the case of Mr. John Trattles, whose colour-vision seems to have been difficult to determine. It is not my purpose to discuss the peculiarities of this case, or the methods of examination used by the Board of Trade. As a worker in this branch of science, however, I may be permitted to say that in any case of supposed defective colour-vision there need be no appeal from the opinion of Sir William Abney, who is so justly celebrated on both sides of the Atlantic for his researches on the perception of colour.

Since, however, in the case of Mr. Trattles, and possibly in others as well, the evidence was not regarded as con-

clusive by all the examiners, it is most desirable that some method should be used about which there could be no doubt whatever. Such a method, I believe, is one founded on the exact measurement of the persistence of vision of colours throughout the spectrum, when the frequency of flicker is at its critical value. The only thing the person under examination has to do is to adjust the speed of a sector'd disc so that the flickering of the part of the spectrum under observation just ceases. The speed of the disc may be automatically registered on a chronograph by electrical means. A series of measurements throughout the spectrum when plotted gives a "persistence curve," which can readily be compared with a similar curve for a normal eye. The great advantage of this test is that it is purely mechanical, and does not involve the handling of coloured materials or the judging of colours in any way by the candidate.

A careful study by this method of twenty-six cases of colour-blindness which I made some years ago ("Persistence of Vision in Colour-blind Subjects," *Phys. Rev.*, vol. xv., 1902) showed such systematic differences between eyes with normal and those with abnormal colour-vision that I am convinced it is the most exact method yet used for the study, not only of colour-blindness, but also of normal colour-perception. I can the more readily express such an opinion inasmuch as this method, though used very extensively by myself, was originally devised by Prof. E. L. Nichols.

In the article in NATURE there is the statement that in the study of colour-blindness "there is none of that accuracy of definition in the scientific picture which rejoices the heart of the physicist." To some extent this may, perhaps, be true, especially for very strong or weak intensities of stimulus. On the basis of the cases I have referred to above, I venture to assert that, for ordinary daylight, there is far more "accuracy of definition" than is usually supposed to exist. I do not know how many cases of colour-blindness must be studied to render the conclusions drawn therefrom reasonably sure, but those to which I refer can readily be divided into distinct classes on the basis of three fundamental colour-sensations, red, green, and violet.

Holmgren, I believe, first pointed out the possibility of the following varieties of colour-blindness:—

Red-blindness	...	...	Defective in one colour sensation.
Green-blindness	...	...	
Violet-blindness	...	...	
Red-green blindness	...	...	Defective in two colour sensations.
Red-violet blindness	...	...	
Green-violet blindness	...	...	Defective in three colour sensations or total colour-blindness.
Red-green-violet blindness	...	...	

In the paper on colour-blindness referred to above, there is, I believe, a demonstration of the existence of each of the above types with the single exception of violet-blindness. This classification, which was arrived at by means of persistence curves, seems to me to be as definite as could almost be desired.

I would therefore suggest this method for the examination of at least doubtful cases of defective colour-vision. The only objection is that the measurements, while simple and easily performed, are somewhat tedious if the spectrum is to be thoroughly examined.

Practice and Knowledge.

MR. AND MRS. HOWARD in NATURE of February 17 show that "the past history of agricultural science furnishes several examples of belated explanations of the utility of practices the value of which has long been a tradition among practical men." In other departments of life practice in advance of knowledge is frequent, and there is one which struck me recently, and may have been observed by others, which is the practice of blowing hot and cold with the mouth which Æsop makes use of in his fable of the "Satyr and the Traveller," and has given rise to the common disparaging saying of "blowing hot and cold."

Some may suppose that the whole explanation of blow-

ing hot and cold may be in the difference in temperature of the two bodies blown on; the Traveller's hands in Æsop's fable were colder than his breath, while the heated mulled wine was warmer. This, however, is only a partial explanation. We have unconsciously acquired the practice of blowing at different temperatures. If we wish to warm our hands we open the mouth wide and direct a slow moving current of air to them, or, more properly expressed, we breathe on our hands. This current has nearly the body temperature; but when we wish to blow cold we purse in the lips until there is only a small opening, as in whistling, and discharge a fine jet of air under pressure. This jet entangles a large amount of air with it, and when it arrives at the hot surface its temperature is much lower than that of the breath. Should the hot surface be also moist, the current of air quickens the evaporation, and so hastens the cooling.

In passing, it may be noticed here that Æsop and the modern use of the expression "blowing hot and cold" seem to have missed the mark. The objects blown on are not the same, but different, and require and receive different treatment. It is no disparagement to say of a man that he blew hot on a scheme which seemed to him to require encouragement, while he blew cold on another he thought ought to be suppressed. Æsop putting the words into the mouth of a being of the type of a Satyr seems to suggest he was not quite sure he had given the highest interpretation of the incident recorded in the fable.

JOHN AITKEN.

Accelerated Velocity of Jupiter's Red Spot Hollow.

THE longitude of the middle of the Hollow has shown a comparatively rapid diminution since the beginning of the present apparition, as the figures below clearly indicate:—

Month	Mean longitude	Diminution	Month	Mean longitude	Diminution
1909 October ...	15° 3'	...	1910 January ...	8° 8'	3° 0'
1909 November ...	13° 3'	2° 0'	1910 February ...	7° 4'	1° 4'
1909 December ...	11° 8'	1° 5'			

From its estimated position on October 25 and February 25 (the first and last dates of observation in the above table), a rotation period of 9h. 55m. 37.9s. (287 rotations) has been deduced. This is 2.7 seconds shorter than the adopted period.

If the present accelerated rate of motion continues until June next, the centre of the Hollow will arrive at λ 0°, or, rather, its longitude will coincide with the zero meridian of system II.

Now this quicker velocity became evident towards the end of the last apparition. An examination of my transit-chart of the Red Spot region for that epoch shows that, up to the beginning of May, 1909, the Hollow exhibited a normal monthly increase in longitude of 1.0°. Subsequently it began to move decidedly quicker, and this acceleration has been well maintained up to the present, as will thus be seen:—

Date	Elapsed rotations	Rotation period h. m. s.	Remarks
1908 Dec. 20 ...	13° 6'		
1909 May 2 ...	18° 1'	321 ... 9 55 42.1	(May 2 chosen as approximate date of change in velocity)
1909 May 2 ...	18° 1'		(The last transit of the apparition was taken on June 12)
1909 June 12 ...	18° 4'	99 ... 9 55 40.9	(Planet invisible for greater part of time between the two dates)
1909 June 12 ...	18° 4'		
1909 Oct. 25 ...	15° 3'	347 ... 9 55 40.5	(Hollow in conjunction with S. Tropical Dark Area, since January 1910)
1909 Oct. 25 ...	15° 3'		
1910 Feb. 25 ...	7° 0'	287 ... 9 55 37.9	

The approximate date when the present accelerated velocity first commenced may be regarded as May 2, 1909.

The recent behaviour of the Hollow, or the Red Spot, is attributed to one well-known phenomenon. Once about every twenty-three months the Great South Tropical Dark Area passes rapidly by the Spot, and on each occasion the latter temporarily participates in its movements. As it is now two years since we witnessed the last of these periodical occurrences, the dark matter, having swept round the planet, is once again involving the region of the Red Spot. The recent accelerated motion of the Hollow, therefore, was fully anticipated.

March 4.

SCRIVEN BOLTON.

A Radium Experiment.

It is usual to demonstrate the ionising property of radium by discharging an electroscope. The reverse experiment of charging an electroscope, or Leyden jar, is more effective, and can be made to ring a bell.

If a wire, about 6 inches in length, is coated with a salt of radium and placed in contact with the knob of an electroscope, the latter will quickly become charged if any charged body is placed within 2 or 3 feet. A small Wimshurst machine is very convenient for the demonstration, as it can be easily turned about to reverse the charge, or placed equatorially, when no effect is produced.

It is a good plan to arrange the leaf of the electroscope to discharge itself automatically to earth at a divergence of about 45 degrees; then the charging is repeated so long as a charged body is in the vicinity. Instead of sending the discharge to earth it may pass into a coherer, and so ring a bell or give a record.

When an induction coil is used it is easy to show that the prepared electroscope will keep on receiving a charge for some minutes after the coil is stopped; for instance, after working an 18-inch coil for one minute, some charge was given to a delicate radium-tipped electroscope when brought into the room four minutes later.

This duration of charge on air can be distinctly shown by filling a large paper bag with charged air and rapidly conveying the same to a Wilson electroscope in another room.

This is obviously due to a residual charge in the air, which persists long after re-combination of mixed ions. This arrangement of a radio-active body near, or, better, in actual contact with, a delicate electroscope is a very sensitive detector. The effect is not quite so good if the radio-active coated wire is placed in contact with the charged body, leaving the electroscope free. Upon exploring the charged air of a room, it is usually found to be divided into two areas of opposite charge; these can be mixed by waving an umbrella, so yielding a neutral mixture.

The fact that a charge is so easily acquired by an electroscope must be taken into consideration during delicate testing, for the mere act of withdrawing a vulcanite pen from the pocket will give a negative charge to a distant electroscope in ionised air.

F. HARRISON GLEW.

156 Clapham Road, London, February 5.

SUBSTITUTES FOR RUBBER.

THE present demand for india-rubber naturally directs attention to those articles which, to a greater or less degree, may serve to replace rubber in its industrial applications, and so help in conserving the supply.

Of such articles a very large number have been proposed. Those in actual use to any considerable extent are, however, relatively few. For present purposes the various surrogates may be distinguished as (1) rubber-substitutes proper, consisting wholly of ingredients other than rubber; (2) composite or "artificial" rubbers, which contain a certain proportion of natural rubber worked up with other substances; and (3) true synthetic rubber, namely, a product containing the rubber molecule synthesised in the laboratory or factory by chemical means from simpler compounds.

At present the first of these classes is commercially the most important. Scores of recipes are in existence, including very diverse ingredients; but the basis of most is a modified oil. At first sight there seems little suggestion of india-rubber in the properties of an ordinary vegetable oil, but a simple experiment will indicate the kind of modification which certain oils readily undergo, and which help to fit them for use as rubber substitutes. If we test the drying properties of boiled linseed oil by spreading a little of it over a slip of glass and allowing it to dry, a film of oxidised oil is eventually obtained, having a certain

modicum of toughness and elasticity. The liquid oil has taken up oxygen, and thereby become converted into a more or less elastic solid. Tung-oil substitute is essentially such an oxidised product, manufactured by heating the raw oil until it has absorbed enough oxygen to cause it to thicken and become solid on cooling, when it is powdered and worked up with a little petroleum.

In a somewhat similar way the oils can be made to take up sulphur, becoming thereby solid, and endowed in some degree with elastic properties. The treatment is analogous to the "vulcanisation" of rubber. "Brown" or "black" substitutes are manufactured by heating the oil with sulphur, a process corresponding to the "hot cure" method of vulcanisation. "White" substitutes may be made by merely mixing the oil, cold, with 20 to 40 per cent. of sulphur chloride; or, better, by first dissolving the oil in a suitable solvent such as carbon tetrachloride. This resembles the "cold cure" process used in vulcanising rubber. Colza oil is largely used for these purposes, but various others are available—linseed, maize, arachis, and castor oils, for example. The chemical reaction involved is a somewhat complicated one, but probably it consists mainly in the formation of what chemists term an "addition-product." The proportion of sulphur taken up by the substitutes varies rather widely, ranging from 5 to upwards of 15 per cent. As would be expected, oils which have previously been oxidised to a notable extent (e.g. "blown" oils) require less sulphur to saturate them than do the natural oils.

"Nitrated" oils are also used as the basis of some rubber surrogates. Thus one well-known product is a solution of a nitro-cellulose in linseed or castor oil which has been nitrated by treatment with a mixture of nitric and sulphuric acids. Other such articles are made by oxidising the nitrated oil with lead peroxide, or by simply heating it in air.

These oxidised, sulphured, and nitrated oils, in one form or another, are largely used as substitutes for rubber. Of the other substitutes proposed, a few examples may be given, to indicate something of their general nature.

First there are those which, while still retaining oil as one ingredient, include also other important constituents. Thus, "Fenton's rubber" is a mixture of oils with tar, pitch, and creosote; which mixture, when digested with nitric acid, gives a toughened mass, and this on heating yields an elastic product simulating rubber. "Russian" substitute, said to be useful for covering telegraph cables, contains as ingredients wood-tar, hemp and linseed oils, ozokerite, spermaceti, and sulphur. "Oxolin" is made by impregnating fibrous material such as jute or hemp with linseed oil, oxidising the oily mass with warm air, and working the product up between rollers into a coherent mass, which can then be vulcanised by heating it with sulphur.

In another category of substitutes oil plays only a subordinate part, or is altogether dispensed with. Thus "Jones's substitute" is stated to be made from various gums and gum-like products as the chief constituents. In W. H. Perkin's patent (23,031/07), gelatine or glue is dissolved in creosote and then treated with some reagent—potassium bichromate, formaldehyde, or tannic acid—which will render the gelatine or glue insoluble; after "setting," the mass obtained is digested with acetone to make it firmer. "Textiloid" has for its ingredients various resins, nitrocellulose, and camphor. As a curiosity in this class may be mentioned "grape rubber," produced from the skins of grapes by means of pressure; it is not, however, a commercial article. Finally, though this can only be

a substitute for rubber in very hard articles, we may mention the interesting material, "bakelite," recently introduced by Dr. L. H. Baekeland. It is a condensation-product of formaldehyde and phenol, which can be moulded as desired, and afterwards hardened.

In what sense are the foregoing articles and their likes to be considered as "substitutes" for rubber? Some persons are disposed to deny them any right to the title, and would look upon them as mere adulterants whenever used partially to replace rubber in what would otherwise be an all-rubber article. Others admit, though sometimes grudgingly, that there is a place which such substitutes can usefully fill. Much depends on what the article is sold as, and on what use it is to be put to. Not all the special qualities of rubber are wanted in all the products for which it is employed. A door-mat is one thing, a bicycle tyre quite another. Where a high degree of elasticity is not really needed, as, for instance, in waterproof goods and electrical insulating work, there is a legitimate field for substitutes which may serve the required purpose. Even here they may not be equal to rubber, but they find their justification in their lower cost. After all, we do not need razors to cut sticks with.

It may be said at once that no substitute is equal to rubber in every respect. Chemically, the latter is a very inert substance—much more so than the substitutes. Hence, even if the latter were not otherwise inferior, they would be less durable than rubber under certain conditions. They are nearly all acted upon more or less readily in circumstances where rubber remains unharmed. The modified oils, in fact, are still oils in the sense that they remain glycerides, decomposable by alkalis, as also by steam under pressure. If used for articles exposed to these agencies, they fail in durability, whatever their excellences otherwise.

The fact that substitutes of this class are readily saponifiable by alkali makes it an easy matter to detect them by analysis when compounded with true rubber. As a rule, the proportion of substitute used is from 5 to 25 per cent., and even the smaller quantity is recognisable.

Of the composite rubbers (or "artificial rubbers," as they are sometimes called), one preparation, which has been made in quantity, and is said to be excellent for many purposes, has for its basis Guayule rubber incorporated with certain gums. Another such article is compounded of natural rubber and some other substance of vegetable origin, probably a latex or a gum, reputed to contain the same chemical elements as rubber and in much the same proportion. Such articles are, of course, only partially "substitutes" for rubber, and their cost rises with that of the latter ingredient. Moreover, if any very large demand for them arose, there is always the possibility that the supply of gums and latices would become insufficient, and the advantage of lower cost would thus tend to disappear.

Coming now to true synthetic rubber; a question often asked is whether there exists any probability of such an article being manufactured and displacing natural rubber, either wholly or to any large extent. Will rubber plantations go the way of madder fields and indigo cultivation? Well, the future is on the knees of the gods. In the face of the precedents just mentioned, to say nothing of others, he would be a bold man who would venture to say that even the best quality of rubber may not some day be made on a commercial scale from cheaper materials such as beet sugar and calcium carbide. But the day is not yet. There are beginnings; there are clear indications of the direction in which to proceed; there is distinct

progress to note. But there is still some distance to go, and the end of the journey may not be even in sight.

India-rubber chemically is essentially a polymerised terpene. An article patented some time ago, and named "turpentine rubber," appears to foreshadow a synthesis of true rubber. Turpentine is a mixture of terpenes, and the article in question was to be obtained by passing turpentine through a hot tube, and treating the resulting vapours with hydrochloric acid. The result is a solid condensation-product; and the idea at the base of the process appears to be the production of polymerised terpenes having some of the elastic properties of rubber.

A more promising, because a more scientific way, is that outlined in Heinemann's patent No. 21,772 of 1907. Here a true synthesis is attempted. It is based upon the well-known fact that rubber is probably a polymer of the semi-terpene isoprene. The first step is the production of the unsaturated hydrocarbon divinyl, $\text{CH}_2:\text{CH}:\text{CH}:\text{CH}_2$. This is obtained by passing mixed acetylene and ethylene gases through a heated tube. With methyl chloride, divinyl yields isoprene [methyl divinyl, $\text{CH}_2:\text{C}(\text{CH}_3):\text{CH}:\text{CH}_2$]; and the isoprene on treatment with strong hydrochloric acid is converted by a union of molecules into a substance closely resembling caoutchouc, if not identical with it. The raw materials, so to speak, are thus acetylene, ethylene, and methyl chloride, which are themselves obtained by any of the ordinary methods, e.g. from calcium carbide, alcohol, and beet sugar residues respectively.

The question is, can this or some other comparatively simple synthesis, theoretically quite possible as a laboratory operation, be translated into a practicable and profitable mode of manufacture on a large scale? One of the first doubts to arise is whether the synthesised caoutchouc will have the physical properties of natural rubber; or whether these, by any course of treatment, can be imparted to it. This doubt resolved, there comes the question of economical production in competition with the natural product. Much time and thought have been spent on the problem of synthetic rubber, and it is safe to conclude that there will yet be many a headache before it is solved. Judging by what is known to have been done rather than by the promises, owners of rubber plantations may for the present sleep peacefully in their beds.

C. SIMMONDS.

REPORT OF THE ROYAL COMMISSION ON CANALS.

THE Royal Commission on Canals and Inland Navigation, the final report of which has recently been issued, was appointed in March, 1906, and consisted of nineteen members, Lord Shuttleworth being chairman. Their instructions were to inquire into the present condition and financial position of the inland waterways of the United Kingdom; to report as to the causes which have operated to prevent the carrying out of improvements by private enterprise; as to improvements desirable in order to complete a through communication by water between the centres of commercial industry, and with the sea; the prospect of benefit to the trade of the country compatible with a reasonable return on the probable cost; the expediency of canals being acquired by public bodies; and the methods by which funds could be provided for their purchase and improvement.

Seven reports and returns have already been issued, and there are four more to follow, including that on the Irish waterways.

The Commission held 106 sittings, and examined 266 canal experts, traders, and others interested in the subject. They personally inspected the most important waterways in this country, and some of those in France, Belgium, Germany, and Holland, and obtained a report from an assistant commissioner on the inland waterways of the Continent.

The final report now issued covers 234 folio pages. It commences with an interesting history of British waterways, and then, seriatim, deals with the different questions submitted for consideration, and concludes with the recommendations at which the commissioners have arrived. These are not unanimous, the minority reports being also given.

Briefly, these recommendations are:—

The formation of a Central Waterway Board, and the transfer to this board of four central lines of canals connecting Birmingham, as the most central trading town of the Midland district, with London, Hull, Bristol, and Liverpool.

If this waterway board, after further investigation, and if satisfied that with regard to general benefit to trade and financial considerations such a course is desirable, it should be empowered to enlarge and improve the existing waterways so as to afford through communication for barges, of 100 tons, between the Midland district and the sea-ports.

The estimate given in the report for constructional works for these four waterways is $17\frac{1}{2}$ millions, the money required for the purpose to be guaranteed by the State. The cost of maintenance, interest, and sinking fund is put at one million.

As already stated, the report is not unanimous. Five of the members sign it with certain reservations, and three members have given separate reports.

The reservations of the five members express their disagreement practically with all the recommendations, their agreement extending only to the historical part, the Scotch scheme, and certain minor matters.

The majority do not appear to have much faith in the scheme they recommend, as they only advise that it shall be carried out if the proposed waterway board is satisfied, after further inquiry, that this would be desirable. They admit that it would not be remunerative, and that the loss would have to be met by the State; that it would be of no benefit to the traders in other parts of England, and that the outlay could only be justified by the advantage it might be to the commerce of the country generally. It is also admitted that even with an improved system of internal waterways a large part of the traffic in goods and minerals must still be carried by the railways, that the system of trade in this country is now so carried on that the traders no longer keep stores of merchandise, but rely on quick and certain delivery of minerals and heavy goods in small consignments, conditions which the canals cannot comply with, and that, owing to this, the introduction of large trucks, which are used for the long distances traversed in the United States, has not been a success here, and this objection would apply with even greater force to barges carrying loads of 100 tons. It is also admitted that if improved waterways were really wanted there would not have been any difficulty in this being carried out by private enterprise.

As to the estimate for carrying out the scheme, this does not include the purchase of the existing waterways, nor the cost of several items such as wharves, warehouses, terminal accommodation, Parliamentary and legal and engineering expenses. In one of the minority reports, the cost of construction and

other matters included in the majority report is put at about one-third more than that given.

The evidence given also clearly shows that there is not any analogy between the conditions attaching to the waterways of this country and those on the Continent, which have been developed and improved by State aid, due to the different geographical conditions and the much longer distances over which inland transport extends.

Of the minority reports, that of Mr. Inglis, the present president of the Institution of Civil Engineers, and formerly chief engineer, and now general manager, of the Great Western Railway Company, is a very able defence of the railway companies and their dealings with canals. He points out the injustice of any State-aided effort to revive an obsolete and unsuitable mode of transit, to the detriment of the railways, which have been constructed entirely by private enterprise, and the shareholders of which receive less than three per cent. on the capital expended.

Mr. Remnant, who is a barrister, states his disagreement to the recommendations of the majority of the commissioners on the ground that these are inconclusive and left for future consideration by the proposed waterway board, and that the evidence does not warrant the conclusions arrived at on economic grounds.

Mr. Davison, who is a civil engineer, criticises the findings as to the transport and financial features, and his report contains in a brief form the substance of all the arguments that can be brought against the policy of State acquisition of the waterways. He is of opinion that it is extremely improbable that the traffic estimated for the proposed improved canals would be forthcoming, and that the estimate of the cost for these does not include important charges, and that no attempt is made to arrive at the ultimate cost.

DR. E. PERCEVAL WRIGHT.

WITH the death of Edward Perceval Wright one of the links connecting the old school of naturalists with the modern students of biology is severed. Wright was born in Dublin in 1834, where his father was a barrister. He early evinced a keen interest in natural history, and his enthusiasm in forwarding its study led him to commence to publish, in 1854, the year after his matriculation in Dublin University, a quarterly journal devoted to natural science. It was called the *Natural History Review*, and its publication was continued until 1866. In this journal, in the *Quarterly Journal of Microscopical Science*, in the *Transactions of the Linnean Society*, the *Journal of Botany*, and in the *British Association Reports*, he published during the next twelve years a series of papers on the fauna of the south and west coasts of Ireland. His undergraduate studies in botany were pursued under the guidance of Prof. G. J. Allman, and as a student he came into contact with W. H. Harvey, who was then keeper of the Herbarium in Trinity College, and of whom Wright always spoke with the warmest appreciation. In 1858 Wright was appointed lecturer in zoology and director of the Natural History Museum of Trinity College. About the same time he was appointed lecturer in botany in the medical school attached to Dr. Steevens's Hospital. It is surprising to find that while he was thus engaged actively in research and teaching, he also found time to prosecute medical studies with such success that by 1865 he had begun to establish a position for himself among Dublin oculists. But he did not remain in practice long, and,

finding it impossible to pursue his medical work together with his duties as *locum tenens* in the chair of botany during the illness of Harvey, who was then the University professor, Wright definitely gave up his ophthalmological work in 1866. During the same period his attention was directed to the finds of fossils in the Kilkenny Coal-measures, and in 1866 he published, in collaboration with T. H. Huxley, an account of the fossil vertebrata from the Jarrow colliery.

In 1867 Wright went to the Seychelles Islands to study the fauna and flora of that group. Unfortunately all his collecting apparatus and preserving materials were lost on the way out by shipwreck. Notwithstanding this misfortune he succeeded in bringing back an important collection of animals and plants, and in the following years was able to publish a series of papers describing the new and interesting forms collected. These papers, together with others on collections made in Portugal and Sicily in 1868, appeared in the *Annals and Magazine of Natural History*, in the Transactions of the Royal Irish Academy, and in the British Association Reports, 1868-76. Shortly after his return from his travels Wright was appointed to the chair of botany in Trinity College, and he held this position until he resigned it in 1904. In 1874 he was elected secretary of the Royal Irish Academy. While University professor of botany, Wright was chiefly interested in herbarium work, and he devoted much labour and enthusiasm to arranging and indexing the valuable collection of plants belonging to the college. Hence it was no ordinary blow to him when, in 1882, through an ill-considered order of the college authorities, he found the whole collection thrown into confusion, and most of his own labours in the herbarium, and those of his predecessors, dissipated. His despondency was short-lived, and he soon buckled to the weary work of arranging once more, and during the next ten years accomplished, practically without assistance, the task of putting the collection into a condition fit for reference. While at this work he was also engaged, in collaboration with Th. Studer, on the report on the Alcyonaria of the *Challenger* expedition.

Speaking from the experience of one who knew only the latter end of Wright's life, his wide human sympathies won the affection of those who came into close contact with him. He was most desirous to forward younger men's work in science, and generously helped them by all the means in his power. It was a pleasure to him to put his varied and often recondite knowledge of the literature of natural science at their disposal. He showed the liveliest appreciation of the results obtained by the more modern generation of biologists. As a teacher he was more than ordinarily successful in stimulating the enthusiasm of his classes and in implanting in them the desire to carry out investigation. He had considerable powers as a conversationalist, and his travelling companions remained his life-long friends. At the same time he was sensitive to a fault, so that he was often misunderstood by those who were not intimately acquainted with him.

Besides his scientific work, he was deeply interested in antiquarian research, and, as president of the Royal Society of Antiquaries, Ireland, exerted himself by every means in his power to forward the investigation of the antiquities of Ireland. His whole career was marked with affection for his University, and some years before his death he presented Trinity College with a valuable collection of botanical books and journals. Since 1904 his health had been gradually failing, and his previous energetic temperament seemed to desert him. The announcement of his death, which took place on March 4, was a grief but not a surprise to his friends.

NOTES.

THE fourth annual meeting of the British Science Guild will be held at the Mansion House, at 4 p.m., on Friday, March 18, under the presidency of the Lord Mayor. An address will be delivered by the Right Hon. R. B. Haldane, F.R.S., and it is expected that Lord Strathcona, the Right Hon. Sir George Reid, Dr. Warren (the Vice-Chancellor of Oxford University), Sir Ernest Shackleton, Sir Alfred Keogh, and Colonel Sir John Young will address the meeting.

WE announce with great regret the death on March 4, in his fifty-fourth year, of Prof. K. J. Ångström, professor of physics in the Royal University of Upsala.

THE death is announced, on March 14, of Dr. H. Landolt, professor of chemistry at the University of Berlin from 1891 until 1905, at seventy-eight years of age.

THE annual general meeting of the Chemical Society will be held on Friday, March 18, when Prof. Harold B. Dixon, F.R.S., will deliver the presidential address, entitled "The Union of Hydrogen and Oxygen in Flame."

WE notice with regret the announcement of the death, on March 14, of Dr. J. C. Brown, professor of chemistry in the University of Liverpool, at sixty-seven years of age.

WE regret to see the announcement of the death of Prof. E. Philippi, professor of geology and palæontology in the University of Jena, and geologist to the German Antarctic Expedition of 1901-3.

MESSRS. SANDERS AND CO., 71 Shaftesbury Avenue, are making arrangements to hold a series of one-man exhibitions from leaders of natural-history work in photography. The first will open early in May, and will be the work of Mr. Richard Kearton. Admission will be on presentation of visiting card.

A REUTER message from Berlin announces that a regular airship passenger service will be started on May 15 from Munich to Starnberg and Ober-Ammergau. A dirigible of the Parseval type will be used, with a gas capacity of 6700 cubic metres. It will carry twelve passengers besides the crew. It will have two motors, each of 100 horsepower, and will make trips alternately to Starnberg and Ober-Ammergau.

THE King of the Belgians has announced his intention to make a grant of 40,000l. for investigations into the nature and prevention of sleeping sickness. Stations for the study of the disease will be established, the number of doctors will be doubled, and missionaries will be trained in preventive measures at Leopoldville. King Albert will also give 20,000l. for the provision of hospitals for natives of the Congo.

THE committee organised a few weeks ago to arrange for a thorough scientific investigation of pellagra appeals for funds to enable it to commission Dr. Sambon to undertake the inquiry. The minimum sum required is 600l., but so far only 230l. has been subscribed, including 150l. promised by the Colonial Office on condition that a further amount of 450l. is found. Subscriptions should be sent to Mr. James Cantlie, honorary secretary and treasurer, Pellagra Investigation Committee, 140 Harley Street, W.

WE have been asked to state that the annual general meeting of the Society of Dyers and Colourists will be held this year in the Municipal School of Technology, Manchester, on Friday, March 18, at 4 p.m., when the retiring president, Prof. R. Meldola, F.R.S., will deliver

an address on "Tinctorial Chemistry—Ancient and Modern." The presidency of the society is to be taken over by Sir Frederick Cawley, Bart., M.P.

THE President of the Board of Trade has appointed a new Advisory Committee on Commercial Intelligence. The chairman of the committee will be the President of the Board of Trade, or, in his absence, the senior Board of Trade representative present. The committee is to hold office for three years. The committee is appointed to advise the Board of Trade (a) on the work of the Commercial Intelligence Branch and on such matters relating to foreign tariffs and other commercial questions as the Board may refer to them, and (b) as to commercial missions abroad or other means of obtaining and diffusing information for the benefit of British trade.

AN international expedition started on March 13 for the Peak of Teneriffe to investigate the effect of high altitudes and sunshine on medical and biological processes. From a note in the *Times* of March 12 it appears that the party included Prof. Pannwitz, of Charlottenburg, the president of the International Commission for the Study of Biological and Medical Effects of High Altitudes and Sunshine; Dr. Barcroft and Dr. Douglas (Cambridge University), representing England; Prof. Zuntz and Dr. Neuberg, representing Germany; Dr. Mascart and Dr. Plasse, representing France; and Prof. Düring and Dr. H. von Schrötter, representing Austria. Prof. Zuntz has already done work in this direction on Monte Rosa, and his observations will be elaborated by the expedition. Preliminary meteorological work has been done by Prof. Hergesell. Dr. J. Mascart, of Paris, has joined the expedition for the purpose of studying Halley's comet under the favourable conditions afforded by the Peak of Teneriffe. Prof. Müller and Dr. Kron, of the Potsdam Observatory, are expected to join the expedition within a week or two.

THE annual general meeting of the Ray Society was held on March 10. The report of the council stated that the society's publication for 1909, a supplementary part of the "British Nudibranchiate Mollusca," has been delayed owing to Sir Charles Eliot's absence from England. For the present year the issue will be vol. ii., part ii., of the "British Marine Annelids," by Prof. W. C. McIntosh, completing the Polychæta. Two volumes are in preparation for 1911, being vol. iv. of the "British Desmidiaceæ," by Mr. W. West and Prof. G. S. West, and vol. iii. of the "British Tunicata," containing the composite species and completing the work. This will complete Messrs. Alder and Hancock's works published by the society. Of other works in preparation, the first instalment of Dr. Malcolm Burr's "Earwigs of the World" will probably be the issue for 1912. An offer by the Rev. Hilderic Friend to contribute a work on the British earthworms has been accepted. Lord Avebury, F.R.S., was re-elected president of the society; Dr. S. F. Harmer, F.R.S., was elected a vice-president; Mr. F. DuCane Godman, F.R.S., was re-elected treasurer; and Mr. John Hopkinson was elected secretary.

THE death of Dr. A. E. Dolbear, for many years professor of physics at Tufts College, Massachusetts, removes one of the most remarkable of American thinkers and inventors. His inability to exploit his discoveries is alleged by his friends to be the only reason why his name is not more widely known. In addition to pioneer work on the telephone, wireless telegraphy, electric waves, and Röntgen rays, among inventions to be placed to his credit are a writing telegraph, a spring balance ammeter, an electric gyroscope to illustrate the rotation of the earth, and a new

system of incandescent lighting. The most notable of his books was "Matter, Ether, and Motion." Prof. Dolbear was born at Norwich, Connecticut, in 1837. After serving as a "bound boy" on a New Hampshire farm, he worked successively in a ship-building yard and a printing office, studying geology, mineralogy, and astronomy in his scanty leisure. Later he "taught school" in Missouri, and worked in the U.S. armoury at Springfield. At the age of twenty-nine he entered the University of Michigan as a student of chemistry, and in six weeks became assistant instructor in that subject. The next year he was appointed an assistant professor in Kentucky University, and then professor of physics and chemistry at Bethany College, West Virginia. While holding the latter post he was three times elected Mayor of Bethany. His main career began in 1874, when the discovery of his scientific ability led to his being called to Tufts College.

A SUMMARY of gales recorded at anemograph stations in 1909 has just been issued by the Meteorological Office. Gales occurred in some part of the British Islands in every month of the year with the exception of June, but naturally gales occurred with far less frequency in the summer than during the winter. The most stormy months were January, October, and December. Strong gales, with a mean wind velocity of 47 or more miles an hour, force 9 of Beaufort notation, did not occur in May, June, or July. The absolute maximum velocity of wind in a gust was at the rate of 90 miles an hour, at Scilly on October 23, but the maximum velocity for an hour for this gale was only 70 miles. The next highest velocity in a gust was 78 miles, at Scilly on January 16, and this was followed, in order, by a gust of 76 miles an hour, at Southport on December 3. Gusts of 75 miles an hour occurred at Pendennis on November 18 and December 2, and at Scilly on December 2-3. No anemograph station had a higher wind velocity than 70 miles for an hour during the year. The summary gives the percentage of frequency of each unit of Beaufort notation at several stations grouped separately for the western and southern coasts combined, and for the eastern coasts and inland stations combined. It is comparatively exceptional at any station for winds of 8 and upwards of Beaufort notation to amount to 1 per cent. of all winds, and winds of gale force are less frequent in the eastern than in the western district.

DR. PENCK, the president of the Berlin Geographical Society, has rightly protested against the idea that there can be any objection to the expedition of any nation helping in Antarctic research on whatever route it may prefer to adopt. The unknown Antarctic area is so vast that any overlap and waste of effort would be deplorable, and the four Antarctic expeditions now being organised will probably be working in sufficiently distant fields to render any formal agreement unnecessary. The German expedition under Lieut. Filchner proposes to start from the Weddell Sea, which will also be used as the base of the American and Scottish expeditions. This part of Antarctica is still absolutely untrdden; the Scottish expedition under Dr. Bruce, which discovered Coats Land, was not able to land on it, and did not even see a convenient harbour. Ice navigation in the Weddell Sea is probably very difficult and uncertain, and Coats Land may be inaccessible in some seasons. The three-fold effort, by increasing the chances of success, is therefore to be welcomed, as at present this part of Antarctica is the most promising of important geographical results. If the three expeditions all establish their landing on this unknown coast, they will each find ample room for independent work.

INTEREST in the North Polar question has again been roused by the refusal of the Naval Committee of the United States House of Representatives to recommend any honour to Commander Peary until he has submitted proofs of his attainment of the Pole. As an expert committee appointed by the National Geographic Society of Washington, and consisting of three such competent authorities as Dr. H. Gannett, Admiral Chester, and Mr. O. H. Tittman, unanimously agreed that Peary reached the Pole, it may be felt that the Naval Committee might have accepted this verdict. The official committee of the House of Representatives is, however, hardly to be blamed for its caution in declining to recommend a Parliamentary honour until the official data have been published, or at least submitted to it. The scepticism felt by some authorities as to Peary's claim is based partly on his great acceleration after leaving his last white colleagues—his pace increasing from 9.6 miles to 26.4 miles a day on the journey north, and to 44 miles on the southward journey until he rejoined Captain Bartlett—and partly on the statement that he took noon observations at the Pole; at that date the apparent path of the sun, as seen from the North Pole, would have been so nearly horizontal that noon observations would have been practically impossible. The National Geographic Society of Washington has been most intimately connected with Peary, and might be prejudiced in his favour; but no such suspicion could be felt in regard to the committee it appointed. The report of that committee was, however, a brief statement of its conviction, and the materials on which its judgment was based are not yet available for public information. If Peary at his most northern point on April 6 was able to determine noon from the sun, he was probably some little distance south of the Pole. To determine the actual mathematical point of the Pole would be impossible during the hasty journey of a lightly equipped sledge party; but any slight error in the observations would not affect the conclusion adopted by most British geographers that Peary reached sufficiently near the Pole to justify his claim. It is to be hoped, however, that his full data will be soon published.

IN *Man* for February Mr. H. A. Rose describes various modes of establishing fictitious kinship now current in the Panjab. Such are the ties between people who have joined in the same pilgrimage; the *páhul* or initiation rite of the Sikhs; the exchange of wristlets by youths, of turbans by men, and sheets by women; adoption by a patron to secure protection. These are important as illustrating the practices of adoption and succession, and they also throw light on the methods by which tribes grew under a process of accretion before the present rigid rules of exogamy and endogamy came to be established.

THE Botet collection of fossil mammals from the Pampa of Argentina, belonging to the city of Valencia, Spain, is one of the most important collections of its kind, but has not hitherto been exhaustively studied or described. It comprises, not only fine specimens of the ordinary ground-sloths and glyptodonts, *Smilodon*, and hoofed mammals, but also several new species and a remarkably well-preserved human skeleton. In view of its scientific interest, Prof. E. Boscá, of the University of Valencia, has arranged to prepare an illustrated descriptive catalogue of the collection, and, as a preliminary to this work, he is at present in London studying the original specimens described by Owen. After visiting the European museums Prof. Boscá will proceed to Argentina to examine the rich collections in Buenos Aires and La Plata.

ACCORDING to the second annual report, the demonstrations and lectures on natural history and economic subjects instituted by the Norwich Museum Association continue to meet with popular appreciation and support. The subjects of the 1908-9 course included the food of birds, flies as disease-disseminators, fungoid diseases of plants, Norfolk soils, and insect fruit-pests.

IN the February number of *Nature* an anonymous correspondent describes two albino Norwegian lemmings, of which one is figured. Such albinos are stated to be extremely rare. In the same issue another writer contributes a notice of the capture by a trawler of the rare fish *Macrurus coelorhynchus*, a species first described in 1842, and of which very few examples have since been taken.

AT the close of an article in the February number of the *American Naturalist* on the question whether regeneration in animals exhibits a repetition of the ontogenetic and phylogenetic processes, Mr. Sergius Morgulis observes that "while the evidence shows that, as a rule, organs originate from similar germ-layers, both in ontogeny and in regeneration, there are also some striking exceptions to the rule. The hypothesis that the method of regeneration is causally influenced by the course of ontogeny is, therefore, quite unnecessary as a corollary. With the elimination of this hypothesis the conception of the atavistic nature of regenerated peculiarities, i.e. the conception of a repetition in regeneration of phylogenetic processes, loses its chief logical support. This last theory, however, is also objectionable, (1) because of its inherent inconsistency, (2) because it depends upon more or less problematic assumptions."

IN a paper entitled "Ungarned Grain," published in the January number of the *Victorian Naturalist*, Dr. T. S. Hall directs attention to the need of further research into the natural history of Victoria. Sponges and protozoans, he points out, are still very imperfectly known, and much the same is the case with regard to crustaceans. Among fishes, it requires to be ascertained whether *Galaxias* spawns in fresh water, while no one appears to be able to produce definite evidence that the Australian eel breeds at great depths in the sea, or if, indeed, it journeys to the ocean at all. Further information is likewise required with regard to the breeding-habits of the native frogs, especially whether or no they require water during the metamorphosis.

TO the February number of the *Zoologist* Colonel C. E. Shepherd communicates an account of the ear-bones of fishes, and more especially the one known as the asteriscus. Three pairs of these bones are developed, of which the sagitta is normally the largest, the asteriscus being the otolith found in the lagena of the sacculus, while the third bone is the lapillus. The form of the sagitta has long been known to be more or less constant and characteristic for the different family groups, and the author shows that the same holds good for the asteriscus, of which he claims to be the first to describe and illustrate the details in a number of species. Attention is specially directed to the great development of the asteriscus at the expense of the sagitta—which is reduced to a minute rod—in the members of the carp family. That this cannot be attributed to a fresh-water life is demonstrated by the fact that in the pike and perch the normal relative proportions of the sagitta and asteriscus are retained, and the reason for the special feature in the carp tribe has therefore still to be sought. As regards the functions of the otoliths, the

author is inclined to support the theory that these include both hearing and the maintenance of the bodily equilibrium.

THE February issue of the Bulletin of the Sleeping Sickness Bureau (No. 14, vol. ii.) appears with cut edges, which will be found a great convenience by readers. It contains the usual useful *résumé* of papers dealing with trypanosomes and their agents of transmission, sleeping sickness, &c.

THE Bulletin of the Johns Hopkins Hospital for January (xxi., No. 226) contains two essays bearing on the history of medicine, one an address by Prof. Osler on Michael Servetus, who was done to death for heresy at Geneva in 1553, the other by Dr. Steiner on Dr. Lemuel Hopkins, a distinguished, though forgotten, American student of tuberculosis, who lived in the second half of the eighteenth century.

IN a paper dealing with the sewage-pollution of shell-fish (*Journal of Hygiene*, vol. ix., No. 4, 1909, p. 412) Mr. James Johnstone points out that at present no public authority possesses legal powers to deal with the question of the contamination of shell-fish. Polluted mussels supplied with clean sea-water undergo purification with rapid partial disappearance of the intestinal bacteria contained in their tissues—in four days, for instance, the number of contained bacteria had been reduced by about 93 per cent.

THE annual report for 1908 of the curator of the technological museums in Sydney has been received. Special reference is made to the collection of building and ornamental stones, in connection with which a brochure, containing coloured reproductions of specimens quarried in the colony of New South Wales, was issued. Notice is also given of a forthcoming volume on the "pines" of Australia, similar to the monograph on the Eucalypts, which will deal with the economics of Australian conifers.

THE action of light on the expansion of buds of woody plants is the subject of a paper contributed by Mr. V. Lubimenko to the *Bulletin de l'Académie Impériale des Sciences*, St. Petersburg (No. 2, 1910). Experiments were made with twigs placed under bell-jars covered with thicknesses of white or black paper. In certain cases a diminution of light retarded development, in others it accelerated it; but in all cases complete darkness caused a marked retardation in the expansion of the buds. The author advances the opinion that light is necessary for the internal chemical changes which precede growth.

THE report on the Botanic Station, Experimental Plots and Agricultural School, Dominica, has recently been issued, and shows that much useful work has been done in distributing among planters crops likely to prove of commercial value or possessing striking features from an ornamental point of view. Much attention has been devoted to the manuring, cultivation, and general management of cacao; the requirements of the lime industry have been investigated, and some preliminary work has been done on the planting of rubber.

IN view of the enormous increase in the number of publications devoted to insect pests, it is becoming more and more necessary to have occasional summaries of the work done in a particular subject. We are therefore pleased to see that a "Bibliography of Sugar-cane Entomology," drawn up by Mr. G. W. Kirkaldy, has been issued as Bulletin No. 8 of the Hawaiian Sugar-Planters' Association. The list of papers seems to be very complete; indeed, the author tells us that a considerable number of apparently worthless notes have been included

'because of the difficulty of drawing a sharp line between what is and what is not useful. The bulletin is divided into two parts: a list of work, arranged under authors, and a preliminary list of the insects, spiders, &c., of the sugar-cane fields, with cross-references to the papers in the first part in which they are mentioned.

A RECENT issue (No. 30) of the *Transvaal Agricultural Journal* contains an article on the olive, urging that more attention should be paid to this crop. The olive was introduced into Cape Colony many years ago, but for some reason or other has never become very popular. It does not bear a paying crop until it is at least six or seven years old, and the oil has to compete with highly adulterated commercial products; but there is a good deal of land in the Transvaal that would give satisfactory crops either with or without irrigation, and one or two trial plantations are already in existence which promise to be successful. We have also received from the Transvaal Department of Agriculture some Farmers' Bulletins dealing with sunflower cultivation, prickly pear for stock food, and the cultivation and preparation of the calabash pipe gourd. The sunflower does not appear to be a very promising crop, as it is expensive to handle and is largely produced in Russia.

PROF. DOVE, of Göttingen, contributes a suggestive article on the aims and methods of commercial geography to Petermann's *Mitteilungen*. The paper deals with the use of the population unit in discussion, the limits of effective capacity of trade routes, the relations of topography and climate to trade, and similar matters, and subjects some of the methods in ordinary use to somewhat severe criticism.

A NEW map showing the distribution of thunderstorm frequency in central and northern Europe, by Dr. E. Alt, appears in Petermann's *Mitteilungen*. The smallest yearly frequency occurs in Cornwall, north-western Scotland, Norway, and the Arctic coast, where the average is under five. The region of most frequent thunderstorms—more than thirty a year—appears in northern Italy and the Carpathians.

FROM a catalogue issued by Spindler and Hoyer, of Göttingen, we see that ninety-six seismographs, designed by Prof. Wiechert, have recently been distributed in various parts of the world. One has been installed by the National Physical Laboratory at Eskdalemuir. The largest of these instruments carries a mass of 17,000 kilos., and the motion of the ground relatively to this is magnified 2200 times. There is, however, a 5 per cent. loss in consequence of the inertia and elasticity of the system of levers. The instrument costs 5000 marks.

BETWEEN July 1 and December 31, 1909, at Shide, in the Isle of Wight, 279 earthquakes were recorded. Each of these records is confirmed by corresponding observations at other observatories, whilst many of them are known to be the surviving efforts of earthquakes which were large at a distant origin. They are therefore of great importance. The instruments at Shide are of the type adopted by the British Association, recording on paper moving at a rate of 4 mm. per minute. During the same interval of time Hamburg recorded 123 shocks, Strassburg 64, and Laibach 42. These great differences in the number of records obtained at different stations appear to be almost entirely due to the type of instrument employed. Those which record on smoked paper are excellent for large disturbances, but fail to record movements which are small.

FROM Dr. Fielding H. Garrison we have received reprints of articles on "Josiah Willard Gibbs and his Relation to Modern Science," and "Physiology and the Second Law of Thermodynamics," which have appeared in the *Popular Science Monthly*, May-August, 1909, and the *New York Medical Journal* for September 25, 1909. The author is assistant librarian to the Army Medical Library at Washington. His writings, notably the one on Willard Gibbs, afford a lucid exposition of the principles of thermodynamics based on an intimate study of the large mass of literature which has centred round this important branch of physics. Most conspicuous, too, is Dr. Garrison's clear appreciation of the debt which experimental science owes to the late Prof. Gibbs for original work essentially mathematical in character. What mathematics can and must do for science, and, on the other hand, what it should never try to do, are points often ill understood, even by workers on physical science that have been trained on orthodox academic lines, and few people have presented the case so effectively as has been done by the army doctor who has written these papers.

A SERIES of experiments have been made recently at the Bureau of Standards at Washington to determine the proper source of light to combine with the mercury arc to produce the best imitation of average daylight, and the results are embodied in a paper by Mr. H. E. Ives in the November (1909) number of the *Bulletin*. It appears that of the ordinary lights, the Welsbach mantle, the carbon, the tungsten, and the tantalum filament glow lamps are all nearly complementary in colour to the mercury lamp, and have, therefore, only to be combined with the latter in suitable proportions to produce satisfactory imitations of daylight. The best proportions are 1 candle-power of mercury light to 0.57 candle-power of Welsbach light, 0.54 of tungsten, or 0.50 of carbon glow light. The watts per candle-power required are 0.80 for the tungsten and 1.4 for the carbon filament combinations respectively. Although the Welsbach cannot be compared in this way, the author finds from the cost of running that the Welsbach mercury combination compares closely with the tungsten mercury one in efficiency.

THE *Journal de Physique* for February contains a communication, made to the Société française de Physique by M. Charles Lallemand, on tides in the earth's crust (see *NATURE*, October 14, p. 457). After a description of the double horizontal pendulum of Hecker, the author explains how the diurnal tilting of the crust, due to the heating of the tropics, may be separated from the smaller semi-diurnal tilt due to the solar tide, and gives diagrams showing the extent of each as determined at Potsdam. The first has a semi-amplitude of the order 10-20 thousandths of a second of arc, the second 2-6 thousandths. Further investigation allows the lunar tide to be determined, and this is found to have a semi-amplitude of the order 10 thousandths. It is hoped by the help of still more sensitive apparatus to detect the half-monthly tide, which should have a semi-amplitude about half that of the semi-diurnal solar tide.

THE Bausch and Lomb Optical Co., 19 Thavies Inn, E.C., has afforded an opportunity to a representative of *NATURE* to examine the Balopticon lanterns which it has just produced and see a demonstration of their functions. The lanterns are designed for transparent or opaque projection, and they combine neatness with efficiency. The arc-lamps are of special design and of small dimensions, and the bodies of the lanterns are designed to suit the lamps, so that the lanterns, as a whole, are delightfully compact. The lamp-case is lined with asbestos, and the

top has the form of a light-tight ventilator, securing a minimum heating effect during operation. The ventilating arrangement is really very satisfactory, and the whole mechanical construction is commendable. The lantern suffers, however, from the merits of its qualities, inasmuch as an ordinary arc-lamp cannot be used with it. Notwithstanding this, the Balopticon, which is made in various models, provides, at a reasonable price, a projection apparatus which is well designed and should be extensively used. An instructive pamphlet referring to the Balopticon lanterns is issued by the Bausch and Lomb Optical Co.

THE first volume in celebration of the jubilee of Prof. Arrhenius was noticed in *NATURE* of February 3. The second volume (*Zeitschrift für physikalische Chemie*, Band 70) has now been issued. It contains forty-five papers by chemists of every nationality. The attention of both supporters and opponents of Arrhenius's theory of electrolytic dissociation may be directed to the article by Mr. G. N. Lewis "On the Use and Abuse of the Ionic Theory."

VARIOUS articles of glassware for laboratory use, including beakers, retorts, boiling, Erlenmeyer, and Kjeldahl flasks, have been forwarded for inspection by Messrs. John J. Griffin and Sons, Ltd., of Kingsway, London, W.C. They are made from a new variety of laboratory glass now being produced by the Rhenish Glass Works, Cologne-Ehrenfeld. This glass is said to be equal to Jena ware as regards resistance to the action of water and of various chemical reagents, whilst having an appreciable advantage in price. The apparatus submitted, though perhaps a little heavier than usual, is well made, and satisfactory in lustre and general appearance. Its refractoriness towards the action of water, acids, and alkalis could, of course, only be proved by trial, but in this respect the behaviour of the glass is attested by certificates quoted, including one from the Physikalisch-Technische Reichsanstalt at Charlottenburg. After a preliminary treatment of the articles for three days, water at 18° C. acting during seven days extracted only 0.002 milligram of alkali (Na₂O) from each 100 sq. cm. of surface exposed, and in three hours at 80° only 0.009 milligram was removed. The material is therefore classed as "water-resisting" glass. Other tests adduced show the extent of the action exerted by boiling solutions of sulphuric acid, sodium carbonate, and sodium hydroxide upon the glass during specified periods, and also the effects of sudden change of temperature. The results go to show that the new glass is a very satisfactory material for chemical apparatus.

IN addition to the books referred to in "Forthcoming Books of Science" (*NATURE*, March 10), the following works are announced:—"Tomatoes and How to Grow Them," F. R. Castle; "Mushrooms and their Cultivation," T. W. Sanders; "Bees for Profit and Pleasure," H. Geary; "Window and Indoor Gardening," T. W. Sanders (*Collingridge*); "A Book about Sweet Peas," W. P. Wright; "Garden Guide," W. P. Wright (*Headley*); "Radio-chemistry," A. T. Cameron (*Dent*); "The History of Chemistry," vol. ii., Sir Edward Thorpe, C.B., F.R.S.; "Last Words on Evolution," E. Haeckel; "The Evolution of Man," E. Haeckel, translated by J. McCabe, 2 vols., new edition; "The Story of Creation," E. Clodd, new edition (*Watts*); "A Text-book of Nervous Diseases," Drs. W. A. Turner and T. G. Stewart; "The Practice of Surgery," W. G. Spencer and G. E. Gask; "The Malarial Fevers, Haemoglobinuric Fever, and the Blood Protozoa of Man," Captain C. F. Craig (*Churchill*).

OUR ASTRONOMICAL COLUMN.

COMET 1910a.—A number of observations, with drawings and photographs, of comet 1910a are published in the March number of the *Bulletin de la Société astronomique de France*. Among others, M. Quénisset describes the observations made at the Juvisy Observatory, where photographs of the comet and its spectrum were taken; and drawings made, between January 21 and February 12.

A photograph taken on January 29 shows the secondary tail extending to some distance from the nucleus on the south side of the main tail, with which it formed an angle of about 25° ; on this date the main tail was estimated to be longer than 62 million miles. The fan-shaped extension towards the sun is also shown, and extended to some 8' from the nucleus, its northern edge showing the concave form discussed by M. Sola.

Comte de la Baume Pluvinel reports that the spectrograms show the nucleus sharply defined in the two principal radiations of the cyanogen band at λ 388, and an intense image of the comet was produced in the hydrocarbon band near λ 472. Between these, the nucleus and tail give a continuous spectrum which presents several condensations, the interpretation of which is still under investigation.

The observations made at the Lick Observatory are recorded in Bulletin No. 174, and show that considerable changes took place in the spectrum between January 19 and 31. The comet was first seen on January 19 as a fan-shaped cloud several times as bright as Venus at its maximum brilliancy, and spectroscopic observations showed the D lines bright, against a background of sky spectrum; D_2 was seen to be much stronger, and to extend further than D_1 . The comet, having considerably decreased in brightness, could not be seen the next day, and a great storm prevented further observations until January 26. It was then seen that, in addition to the D lines, the regular cometary bands were present. On January 27 the same features were recorded, and an additional brightening was seen just to the right of D. A photograph of the spectrum showed a great similarity to the spectrum of comet 1907d, as photographed by Dr. Campbell, the continuous spectrum being relatively weak as compared with the bands. Observations made on January 31 showed that the D lines and the red condensation had disappeared, and that the spectrum of the tail was continuous, extending to a distance of 1° from the head.

On February 1 and 2 spectra were photographed with a prismatic camera, and show that the light of the tail is practically all within the visual region, extending towards the violet but a short distance beyond λ 467. Dr. Wright suggests that it may be due to sodium vapour rendered fluorescent by the intense sunlight; this assumption might also account for the faint band seen on the red side of the D lines.

Dr. Albrecht also made spectroscopic observations with a newly designed grating spectrograph of high dispersion attached to the 36-inch refractor. The resulting photographs, on January 27, show the D lines, D_1 being not more than one-third the intensity of D_2 . The light from a sodium flame was employed as a comparison spectrum, and measures made of the radial velocity of the comet, which was found to be +66.1 km., and is believed to be trustworthy within 2 or 3 km. Dr. Albrecht suggests that such observations might be useful in determining the orbit of a comet in rare cases, such as the present, when it is difficult to determine accurate positions. Subsequent observations showed that between January 27 and 30 the intensity of the D lines must have decreased ten-fold.

Photographs taken by Messrs. Merrill and Oliver cover the period January 26 to February 1, and show the general changes and details well, but no sharp narrow streamers and bright knots or condensations are anywhere indicated.

In No. 610 of the *Astronomical Journal* Prof. Barnard reports that cloudy weather prevented photographs being taken at the Yerkes Observatory during the period of the comet's greatest brilliancy, except on January 21 and 24, when fair negatives were obtained. A photograph taken on February 3 shows the extension beyond the head, towards the sun, to be $12'$ long. This extension is a prolongation of the southern edge of the main tail, and is shown on all three photographs taken on that date.

A further continuation of Dr. Kobold's ephemeris is given in No. 4393 of the *Astronomische Nachrichten*, and shows that the comet is still moving very slowly northwards through Pegasus, the position for March 17 being 22h. 27.6m., +16° 32'. An observation made by Herr Pechüle on March 6 gave corrections of os., +0.5', and showed the magnitude to be about 9.5.

HALLEY'S COMET.—Numerous photographs of Halley's comet have been secured, at the Lick Observatory, with the Crossley reflector and other instruments. The negatives taken on December 11, 12, and 13, 1909, show the coma and faint traces of a cone-shaped tail; as the angle made by lines from the comet to the earth and sun, respectively, was, on that date, less than 2° , this indicates a fairly well-developed tail. A photograph secured by Mr. Olivier with the Crocker telescope on January 28 shows a tail nearly 1° long. On a negative taken with the Crossley reflector on February 4 a very fine, sharp, stellar nucleus, less than $5''$ in diameter, is seen, and the tail appears as a narrow, sharply defined cone; but similar photographs secured on February 10 and 11 show an entirely different form of tail, the narrow quiescent cone having given way to a tail having several fine streamers radiating from the head; the two longest streamers are straight, and can be traced to a distance of $20'$ from the head, while the most southerly one is curved. These changes are also shown on the photographs taken with other instruments, where the tail can be traced to a distance of $40'$, and doubtless indicate a sudden burst of activity during the first week in February (Lick Observatory Bulletin, No. 174, p. 183).

PIDOUX'S COMET.—It now appears probable that the report of the discovery of a new comet at Geneva was a mistake. A plate exposed through clouds on February 20 showed a V-shaped nebulous form near Halley's comet, and before the identification of this object could be completed, the news arrived that a new comet, in the same position, had been discovered at Cardiff. A plate exposed on February 14, on the same region, showed no trace of the object; but a similar form was seen on the edge of a plate taken on February 16; but on a photograph taken at Heidelberg on February 10, which covers the region where, according to calculation, the alleged comet should then have appeared, there is no trace of any such object. As no control plate is available, the existence of the reported comet cannot be confirmed (*Astronomische Nachrichten*, No. 4392).

THE INTERNATIONAL AËRO AND MOTOR BOAT EXHIBITION.

THIS exhibition opened at Olympia on March 11, and will continue until March 19. The Society of Motor Manufacturers and Traders, Ltd., supported by the Aëro Club of the United Kingdom, are responsible for the organisation, and deserve commendation for the fine collection of machines on show. It will be remembered that the first exhibition of this kind, organised by the same society, was held last March. Great advances have been made in flying machines during the interval, and the fact that British makers do not intend to be left behind will be evident to anyone who visits Olympia this week. A pleasing feature of the present exhibition is the almost entire absence of "crank" ideas, especially in the full-size machines shown. Such are almost inevitable in any collection of models, but even the model section contains many fine examples of thoughtful design and skilful workmanship.

Monoplanes comprise by far the larger number of machines in the exhibition. Apart from any inherent advantages of this design, such as space occupied, convenience in dismounting and packing for transit, and lightness, there is no doubt that its popularity, both with makers and buyers, is owing to Blériot's flight across the Channel last summer. There are twenty monoplanes, nine biplanes, and one triplane, all of these being full-size machines. In addition, there are two balloons, a dirigible, and a large number of engines and accessories shown separately, as well as motor-boats and launches. In practically every case it is evident that the brains of a skilled engineer have been brought to bear on the design and construction.

Profiting by past experience in metal propellers and their dangers, most of the propellers shown are constructed of wood, built up so as to secure the grain everywhere running straight from tip to tip. A few makers are bracing the lattice girder forming the main frame in the monoplane type with wood in preference to piano wire, although the use of the latter for bracing is still general. In several cases piano wire has been abandoned for bracing the wings, the preferable material for this purpose being light stranded wire rope and flat steel ribbon.

The engines are generally of the fixed cylinder type, although a few rotary engines may be observed. Water-cooling is more usual than air-cooling. In biplanes the engine and propeller are usually situated behind the pilot; in monoplanes these are generally in front of the seat, although in the case of the Petre monoplane the propeller is at the extreme rear of the machine, and is driven by a tubular shaft from the engine which is placed behind the pilot; but few makers warp or alter the inclination of the main wings for steering or for stability; in most cases ailerons are fitted to biplanes, and in the monoplane type the tails are made movable for vertical and horizontal control. Practically all wings are double surfaced. More firms are paying attention to the matter of reducing the number of levers required for control. For example, in the Humber machines all control is effected by a single steering wheel mounted on a pillar which can swing, and the steering-wheel spindle is capable of axial as well as rotary motion in the pillar. These movements independently operate all the control; there are no foot or hand levers.

It is exceedingly gratifying to notice the large number of British-built aeroplanes; some sixteen of the total machines on show have been built entirely in this country; of the engines shown separately, by far the greater number are British-built. There is no doubt that a great awakening to the possibilities has taken place among our engineers, and that no efforts have been spared during the past autumn and winter to develop the manufacture of flying machines. Many of these British machines have been tested, and when we possess, as no doubt we shall before the coming summer is over, a reasonable number of British pilots having experience with the machines, we shall be able to regard this country as no longer behind in this important industry. The limitations of space forbid us noticing particularly any but a very few of the machines in the exhibition.

Of machines shown by members of the Royal Aéro Club, one of the most interesting is a Short Wright biplane, the first of its kind built in England, and belonging to the Hon. C. S. Rolls. This machine has flown about 100 miles, and has won many prizes. In general design it closely resembles the machines used by the Wright Brothers. There are twin screws, chain driven; the dimensions are 40 feet by 28 feet by 8 feet. Another Short biplane is shown belonging to Mr. J. T. C. Moore-Brabazon. This machine measures 45 feet in breadth, 28 feet in length, and 8½ feet in height. The weight of machine complete, with aviator and in flying order, is 1500 lb.; the actual lifting surface is 450 square feet. The machine is fitted with Short's patent front elevators and balancing planes, and has their system of trussed girder skids. Twin propellers are fitted running in the same direction; this is the first time this principle has been adopted, and has proved to be very successful. A front vertical rudder has been substituted for one in the rear for directional steering. The speed is about 48 miles per hour, and the machine has made a large number of flights, that of March 1, 1910, being of 32 minutes' duration in covering a distance of about 25 miles. This machine won the 1000l. prize (*Daily Mail*) for the circular mile, all-British made. A monoplane built by Messrs. Holland and Holland, and belonging to Mr. B. Nicolson, is also shown.

Messrs. Short Bros. also show a new biplane built for the Hon. C. S. Rolls. The engine is a Green four-cylinder, 105 mm. by 120 mm. bore, giving 38 horse-power at 1200 revolutions per minute. The lifting surface is 270 square feet, and the weight complete is 700 lb. In the annexe is a Sommer biplane, also owned by the Hon. C. S. Rolls. This machine is fitted with a Gnome engine (rotary). Messrs. Humber, of Coventry, show three mono-

planes of their own manufacture. The workmanship and finish of these machines are beyond reproach. Messrs. A. V. Roe and Co. are represented by a triplane of all-British make. This machine is 20 feet long by 20 feet span, and is 9 feet high. The main planes, and also the tail, consist of three planes arranged one over the other, the total supporting surface being 320 square feet. The weight without motor and fittings is 150 lb. All the planes are under control, so that the angle of attack can be adjusted from the steering wheel, and the main planes can be warped. The seats for the pilot and one passenger are behind the main planes, and the engine and propeller in front. Machines of this type have made frequent flights with a motor of 9 horse-power only, and start quickly, often in twenty yards.

Messrs. Blériot have three of their models No. XI. cross-Channel type of monoplane in the exhibition. These machines are fitted with a three-cylinder Anzani motor giving about 25 horse-power; bore, 105 mm.; stroke, 130 mm.; weight in full running trim, 60 kilograms. The propeller is made of layers of French walnut, of diameter 2.1 metres, and weighs 4½ kilograms only; its speed is from 1200 to 1700 revolutions per minute. The monoplane measures about 25½ feet across the wings, and is about 26 feet long; the sustaining surface is about 14 square metres. The total weight of the machine is about 300 kilograms, including the pilot and fuel for a two-hours' run. The speed is about 68 kilometres per hour, and the machine can lift and sustain in flight about 22 kilograms per square metre of supporting surface, i.e. about 5 lb. per square foot.

Messrs. A. Darracq and Co. show the latest type of Farman biplane. The length is 39 feet, span 32½ feet, height 11 feet 4 inches. The supporting surface is 480 square feet, and the weight without engine is 1050 lb. A Chauvière propeller 8½ feet in diameter is placed at the rear of the main planes. The motor on the machine shown is a 50 horse-power Darracq four-cylinder horizontally opposed; bore, 130 mm.; stroke, 120 mm. The cylinders are water-cooled, and the weight, with oil and water pumps and carburettor, is 242 lb. The machines are made under the personal supervision of Mr. Henry Farman at the Châlons Camp, in France.

The Demoiselle machine of Mr. Santos-Dumont shown at the Clement-Bayard stand attracted great attention. This is claimed to be the smallest, lightest, and fastest aeroplane in the world. The length is about 20 feet, width about 18 feet, supporting surface 110 square feet, weight 242 lb. with a two-cylinder water-cooled motor. The radiators are arranged close up under the wings, one on each side of the main frame. The horizontal and vertical planes forming the tail are rigid as regards one another, but the tail can turn as a whole on vertical and horizontal axes for controlling directional and elevating steering. Another interesting exhibit at this stand is the engineer's cab of the dirigible Clement-Bayard. We noted in the engines shown at this stand the care which had been taken to lock all nuts and fastenings so as to prevent them becoming loose.

A Grégoire Gyp monoplane shown by the Fiat Motors, Ltd., did not arrive until ten o'clock on Friday evening. It is interesting to know that the machine was ready for exhibition shortly after eleven o'clock on the same night, showing the ease with which the monoplane type can be erected. The Phoenix Radial Rotary Motor Co., Ltd., show part of a twelve-cylinder rotary engine under construction for Mr. Cody.

The Motor Supply Co., Ltd., show an Avis type monoplane built by the Scottish Aeroplane Syndicate of London. This machine is entirely of British make, except the 30 horse-power Anzani engine. The machine is of the non-lifting tail type, 27 feet wide and 27 feet long. The main planes have a surface of 160 square feet. The weight without motor is 280 lb.; the weight of the motor complete is 150 lb. Messrs. Mulliner, of Long Acre, show a monoplane of entirely British make. This machine has an improved system of warping the trailing edge, combined with the action of a non-lifting type of elevator and a rudder at the rear. Messrs. Mann and Overtons, Ltd., of Pimlico, show a monoplane of the Santos-Dumont type. An English-built monoplane is shown by Messrs. R. Lascelles and Co., Ltd., and an all-British biplane by

Messrs. George and Jobling; both these machines possess interesting features in the matter of control. There are also monoplanes by the Star Engineering Co., Ltd., of Wolverhampton, and by Handley Page, Ltd., of London.

It is quite impossible to deal adequately with all the points of interest in the exhibition. That its success is assured, and that its effects will be far-reaching, are evidenced by the large numbers of visitors, most of whom appeared to be keenly interested and full of inquiries.

EXPLORATIONS IN THE GLACIER TRIBUTARIES OF THE SHAYOK RIVER, KASHMIR TERRITORY.

IN the *Times* of December 21, 1909, reference was made to certain discoveries by a party consisting of Dr. E. G. Longstaff, Dr. A. Neve, and Lieut. A. M. Slingsby in the Kashmir Himalaya. The *Geographical Journal* of November, 1909, also had an article, based upon an account of the tour, written by Dr. Neve in the *Times of India* of September 4. A few remarks concerning the addition to Himalayan geography referred to in these communications may be of interest.

The topography of this part of Baltistan requires explanation; if the atlas sheets are examined, it will be seen how very few trigonometrical points are to be found east of longitude 77° . They are much fewer than in the portion of Baltistan I had to survey on the Lower Shayok and Indus, and the branches of the Shigar tributary of the latter river. The difficulties of penetrating into these out-of-the-way valleys were very great, and it was almost a superhuman task for Mr. Ryall and other assistants to produce, in the limited time given them, a better or more accurate idea of its geographical features. Very few of the glaciers were followed up, or can be followed up, so their sources were merely sketched in by eye from a distance. Very many tributaries are inaccessible, either from their rocky, wall-like sides, or the stream being too deep and rapid to ford, there being no bridges, or the means of making them. Thus the topography can only be classed as rough reconnaissance. The Saichar valley and its glacier was not ascended far, if at all, and even the distance and size Mr. Ryall assigned to it some twelve miles N.W. from Saichar would in nature appear to be its total length; it probably has a bend, and if straight a distant ice fall, or a local narrowing might give the appearance of a watershed. I have not heard of Mr. Ryall for very many years; if he is still living he would be able to tell us whether he ascended the glacier to any distance. His field book, if it is to be found, would give much information as to where he went. There would be his boiling-point observations, and the notes he made in it.

There can be no absolute accuracy in the topography at the head of the Kondus Valley, south-east of Snowy Peak K. This valley, I would point out, is well worthy of further exploration, because it is possible some high point on its eastern side could be reached from which a view would be obtained of the higher portion of the newly-discovered Terim Glacier and the snowy range which bounds it on the north-eastward. Concerning the Terim Glacier extension of the Saichar, the discovery alters the position of the main range, which may be taken as fairly well laid down up to lat. $25^\circ 30'$, long. $77^\circ 30'$. North of lat. $35^\circ 30'$ up to about lat. $35^\circ 45'$ and long. 77° has certainly to be mapped. This is some forty-five to fifty miles in length, and lies fifteen miles or more further to the north and eastward. It is to be hoped that Colonel Long, the present Surveyor-General of India, will see his way to depute one or two of his best officers to extend the triangulation, fix more points, and accurately lay down this corner on a plane table—an attractive, delightful summer's work for someone.

That very high peaks in this corner, lying to the east of K₂ and Gusherbrum, escaped the view of the triangulators when they were observing at the principal stations of the Indus River and Changchenmo series is not surprising. The high mass between the head of the Nubra River and the Shayok, 20,000 to 22,000 feet, would hide much. From trigonometrical stations east of Leh, the same portion of the main water parting is shut out by another lofty mass 22,000 to 25,000 feet, dominating the Shayok Valley on its northern side.

The Shayok series was a very short one, the stations of observation did not extend to lat. 35° , and from the two highest stations, Ajanlung, 19,903 feet, and Telthep, 19,705 feet, overlooking and south of the Shayok Valley, peaks at the head of the Saichar Glacier would not be visible owing to the intervening mountain masses.

A point of interest is the great length of the Terim Glacier, estimated at forty-four miles, next its position and direction, in connection with the trend of the ranges in Ladak and the mountain area both to the eastward and westward. This great glacier, as described, would appear to occupy a blank on the map, and, like a piece of a puzzle, exactly where it might be expected to fit in. This the topography at the head of the Saichar Glacier and the line of the main water parting did not previously indicate on the atlas sheet.

A valuable compilation was published in 1907, viz. "A Sketch of the Geography and Geology of the Himalaya Mountains and Thibet," by Colonel S. G. Burrard, R.E., F.R.S., superintendent Trigonometrical Survey, and H. H. Hayden, superintendent Geological Survey of India. In 1883—presidential address, Geographical Section, British Association—I made an attempt to bring the remarkable parallelism of the mountain ranges into some sort of systematic sequence from the plains up to the loftiest parts of the Himalayan chain. Correctness in detail was not to be expected over such an extended area, yet it is some satisfaction to find the general principle underlying my plans and sections has been accepted by officers of the Trigonometrical and Geological Surveys. My Shayok Kailas range they call the Kailas; for my Mustakh axis, which I considered one of the most important, they adopt that of Karakoram; but I am now inclined to think, from what Dr. Longstaff reports, that yet another well-marked elevated range is indicated by an extension of Younghusband's Aghils, on the northern side of the Oprang Valley, continued to Longstaff's new peak, 27,610 feet, about long. 77° and lat. $35^\circ 30'$ (*vide Geographical Journal*, January, 1910, p. 65). I am doubtful if this assigned position is correct, for on the atlas sheet it is close to the head of the glacier called Sherpi Gang, in the Kondus Valley. The position long. $77^\circ 20'$ and lat. $35^\circ 40'$ given in the *Times of India* would appear to fit in best with the general account. The Karakoram pass and watershed lie some forty miles to the north-east of the Saichar Glacier, and must therefore fall on a still more northern axis of elevation, running in the direction of the Lingzhithang plain, and quite distinct from my Mustakh one.

From Leh the direction of the Ladak axis or range is indisputably to the south-east, and it leaves the Pangkong Lake and Rudok well to the north, but the west and east wrinkling exhibited in the ranges much further to the north has not been so definitely established owing to the absence at many points of geological data to link them up; this is particularly the case with the Karakoram pass and the country north of the Changchenmo range.

The topography of this area leads me to notice what is written in the above-mentioned work by Colonel Burrard and Dr. Hayden, part ii., p. 100:—"Even the great Karakoram peaks themselves seem to follow two alignments. The Masherbrum peaks and peak 63 or K₁₂ (table v. of part i.) surmount a ridge parallel to that on which the peaks of K₂ and Gusherbrum stand, and at a distance of ten miles from it." This feature can thus be explained.

The Masherbrum ridge westward from K₆, 25,119 feet, the peak which the Duke of the Abruzzi ascended to 24,583 feet last summer, represents, together with the Mustakh Pass granite axis, one main broad line of elevation. The Baltoro Valley occupies the trough scoured by its glacier along the strike and junction of the stratified rocks of the Masherbrum side, which originally lay up against the granite, and may very possibly have been once continuous over it. The southern Masherbrum ridge is, in fact, only a secondary feature, the result of denudation.

I cannot say for certain what K₂ is composed of—probably not granite, more likely of the metamorphic and stratified series coming in on the north of the axis. This may be explained in more detail.

The stratified rocks, schists and slates, limestones and sandstones, a series of enormous thickness, composing the

Panjal and Zanskar systems, occupy, as it were, ellipsoid basins or long troughs in the granite, and crushed up against it. Lines of drainage often follow the line of junction, breaking through the basal granitoid rock at certain points. We find a very instructive section on the Panmah Glacier, further west, which has cut its way down through the main granite axis, having here a breadth of ten miles or so. Further up the glacier, at Drenmung, where it bends round to the north-west, this main source, the Nobundi Sobundi Glacier, lies parallel to the line of the main water parting between the Indus drainage and the Oprang Valley. The broad river of ice is bounded on the south-west by the granite, on the north-east by a great series of stratified rocks forming the elevated main range for many miles and dipping to the northward. The breadth of granite continues thence for fifteen miles south-east, and then another twenty-five miles east towards Gusherbrum, and comes in, in the Baltoro Valley, forming the wonderful spurs and peaks of its northern side. Across the breadth of the glacier, moraine after moraine, for some three miles, the precipitous southern flank of the Masherbrum Ridge rises, all of stratified rocks, and Gusherbrum, at the eastern end, appeared to be of the same series, but closer to their junction with the granite, and vertical.

At Gusherbrum, K6 and K, a slight change in the strike of the whole mountain mass takes place. The head of the Terim Glacier, according to Dr. Longstaff, extends up to Gusherbrum, and he has proved that this glacier is the head of Ryall's Saichar Glacier, which, so far as it is shown on the atlas sheet, has a direction N.W. to S.E., the line of valley trough being continued eastward in the Nubra to the junction of that river with the Shayok. There seems a probability, arising from the interesting fact mentioned by Dr. Neve of granite rocks on the south of the Terim Glacier, stratified rocks on the north, that the former correspond to those north of the Baltoro Valley, and that the stratified series from near Gusherbrum continues east and forms the water parting between the Oprang Valley and the Terim Glacier. If such be the case we have a continuous strike of granite along the Nubra River to Changlung, *vide* Lydekker's map, *Memoirs of the Geological Survey*, vol. xxii., thence to the Marse mik La, which I know, to Nyak Tso of the Pangkong, and so on towards the Aling Kangri range, leading into Dr. Sven Hedin's Trans-Himalaya.

To return to the Masherbrum ridge, this finds its counterpart further west, and is represented by those remarkable sharp-pointed peaks, No. 11, B16, and B15, on the east side of the Biafo Glacier. This great glacier and the Hisper, indicating the position of this Mustakh axis as far as Hunza Nagayr, is truly one of the most striking physical features to be met with in the Himalayan chain.

H. H. GODWIN-AUSTEN.

BOTANICAL PAPERS FROM CAMBRIDGE.¹

THE six papers referred to below are the work of members of the vigorous school of botany (including palaeobotany) which now flourishes at Cambridge.

(1) Miss Stephens's investigation, begun in the botanical laboratory of the South African College at the suggestion of Prof. Pearson, is of considerable importance. The Penæaceæ are a small order of heath-like shrubs, allied to the Daphne family, and limited to the south-western region of Cape Colony. Out of the five genera, three, represented by six species, have been examined, and have all been found to agree in the essential points.

The ovary has four carpels and four loculi, each of

which contains from two to four anatropous ovules with two integuments. The embryo-sac is derived directly, without intermediate cell-formation, from its mother cell; hence the reduction-division takes place in the nucleus of the embryo-sac. Four nuclei are first formed, and then each of these divides into two. The four pairs of nuclei are usually found lying cross-wise, one pair at each end of the sac and the other two at the sides. Each pair then divides again; four free nuclei, one from each group, fuse to form the primary endosperm-nucleus, while the three remaining cells in the four groups assume more or less the arrangement and appearance of an egg-apparatus. Thus the mature embryo-sac normally contains four peripheral groups of cells, each group resembling an egg-apparatus, and four nuclei in the middle, fusing to form the endosperm-nucleus; occasional variations from the prevailing arrangement were observed. Usually it is the ovum belonging to the group nearest the micropyle which is fertilised. In the case of this apical group fertilisation has been repeatedly observed; there is no evidence that parthenogenesis occurs. The interesting question whether the quadruple endosperm nucleus is fertilised, as in typical angiosperms, by one of the male nuclei, has not yet been determined. The embryo is remarkable for the absence of a suspensor, the small development of the cotyledons in comparison with the bulky hypocotyl, and the absence of a root-cap up to the time when the seed is ripe.

The significance of the peculiar type of embryo-sac in this order (only paralleled, as yet, by a species of *Euphorbia*) is fully discussed. The interest of the question is enhanced by the consideration that the Penæaceæ appear to be a dying-out family, as suggested by their limited distribution, the non-germination of the seeds in culture, and the extreme rarity of seedlings in nature. The author sums up her conclusions as follows:—"This embryo-sac is probably to be regarded as a derived form, with all four megaspores included in its development, rather than as a primitive one. . . ." "It is suggested that in either case its endosperm is formed, like that of *Welwitschia*, by a fusion of potential gametes, all the nuclei in the sac being looked upon as potential or reduced gametes."

(2) The genus *Saxegothea* is represented by a single species, a small, yew-like tree growing in wet woods on the upper slopes of the Chilean Andes. Mr. Stiles has made a detailed investigation of the anatomy of both vegetative and reproductive organs, and confirms the position usually assigned to the genus as a member of the Podocarpeæ, a tribe of taxoid conifers. At the same time, he finds many points in common between *Saxegothea* and the Araucarieæ. He unnecessarily weakens his case by the statement that "*Saxegothea* differs from the Araucarieæ in having the ovule inverted" (p. 218); the ovule is, of course, inverted in both groups alike.

The author concludes:—"Thus it would seem probable, as Lindley said in his first description of the plant [1851], that *Saxegothea* is a transition of a remarkable kind between the Pinaceæ and the Taxaceæ." The conclusion is interesting, as it supports the view that the Coniferales are essentially a monophyletic stock.

(3) The authors, Messrs. South and Compton, were so fortunate as to have at their disposal a plant of the Mexican cycad, *Dioon edule*, no less than 120 years old; it had spent thirty years of its life in the Botanic Garden at Manchester. In so old a plant—65 cm. in height and 80 cm. in girth—the narrowness of the vascular zone was remarkable; it was only $\frac{1}{2}$ cm. in thickness, one-fifteenth of the radius of the stem; this poor development of the conducting system is accounted for by the small number of leaves functional at one time, the slow rate of growth, and the xerophilous habit. The structure of the stem is normal as in *Stangeria*, showing none of the vascular anomalies characteristic of some other cycadaceous genera. Within the stem two dome-like systems of internal strands, running out into the withered peduncles of bygone cones, were observed. The authors accept Count Solms-Laubach's interpretation that the growth of the stem is sympodial; each cone terminates the main axis, while the stem is continued by one of a pair of opposite buds. The presence of two such buds (one being abortive) is a new

observation of the authors', and is interesting from the analogy with the early Mesozoic genus *Anomozamites*, in which each fructification is in a terminal position in the fork between two vegetative branches.

The anatomy of the peduncle agrees with that in *Stangeria*, centripetal xylem occurring in the upper part, while small, blind-ending bundles, often of concentric structure, are present in the basal region.

Nodules, perhaps comparable to those of the Leguminosae, occur on the roots. The authors regard the sympodial organisation of *Dioon* and *Stangeria* as primitive, and hold that the monopodial growth of the trunk observed by Prof. Pearson in *Encephalartos* is clearly a later development, and connected with the production of several cones simultaneously.

(4) Though for many years past no one has doubted that the fossil cones grouped under *Calamostachys* were the fructifications of calamites, the direct proof of continuity has so far been lacking in the case of those specimens which, at the same time, show the internal structure preserved. In this memoir Mr. Thomas records the discovery of the well-known petrified fructification *Calamostachys Binneyana* in connection with the vegetative organs of the plant to which it belonged. He has also made some interesting incidental observations—the probable presence, below the lowest whorl of bracts, of a disc comparable to the annulus of *Equisetum*, the presence of hairs (rare in this family) on the axis, and the close agreement in structure between the bracts and the vegetative leaves. The author has also observed impressions of cones and leafy shoots, which he refers to the same species with the petrified specimens, identifying both with the *Paracalamostachys Williamsoni* of Weiss and the *Asterophyllites (Calamocladus) grandis* of Sternberg. He suggests, with good reason, that the name *Calamostachys Binneyana*, hitherto used for the structural specimens, may represent a type rather than a species. In discussing the morphological questions involved, the author rightly emphasises the homology between bracts and foliage leaves, so clearly brought out in his specimens.

(5) *Utricularia brachiata* is a small species from the Sikkim Himalaya discovered by Sir Joseph Hooker; it grows, at an altitude of about 11,000 feet, on the trunks of *Abies Webbiana*, among moss. The plant consists of a flowering stem two or three inches high, a few reniform leaves, and several slender runners bearing tiny bladder-traps and tubers. The point of main interest, as in other species, is the morphology of the runners in relation to that of the leaves. The simple view that the "leaves" are phyllomes and the runners caulomes is rejected, on account of the innumerable transitions between the two, and the fact that the bladders are found indifferently on both. The theory that the runners are specialised leaves has been strongly maintained by Goebel, but the author, Mr. Compton, favours the alternative interpretation, advocated by the younger Schimper, that the runners are of the nature of stems, and that the "leaves" have been derived from similar organs by a process of flattening—that they are, in fact, phylloclades. The question is one of much difficulty; the author puts his case well, but we take exception to the argument that his interpretation "is without the theoretical demerit of the contrary view, in that it does not tend towards an abolition of morphological categories." The question as to the modifications that may have taken place in the organs of the genus *Utricularia* must surely be decided without reference to the convenience of the theoretical morphologist.

(6) Mr. Bartlett's little paper is a description of two flowering shoots of the common woundwort, found at Medstead, in Hampshire, which showed certain floral abnormalities, increasing in degree towards the apex of the shoot. In the extreme cases the pistil was represented by two hairy, foliaceous carpels, usually united by their edges below, and bearing abortive ovules. This teratological condition confirms the conclusion, based on development, that the pistil of *Labiata* is really bicarpellary, though the ovary is quadricellular. The floral axis produced at its apex, within the modified ovary, one or more flower-buds—a case of Masters's "median floral proliferation."

D. H. S.

THE PRODUCTION OF BLACKWATER FEVER.¹

DRS. WAKELIN BARRATT and Warrington Yorke have pieced together the result of their investigations, in the form of a report, undertaken for the blackwater fever expedition to Nyasaland. The object of the work was to determine how blackwater fever is produced; in brief, it may be stated that the authors have failed to accomplish this object. Incidentally, the work was intended to throw light on many of the uncertainties connected with the fever, and in this respect they have succeeded.

In simple language, blackwater fever is a fever which occurs in persons who have been treated with quinine, usually for malaria, and the clinical connection between the fever and the quinine has been placed beyond dispute. The authors, after studying the processes of the dissolving up of red blood corpuscles under a large variety of conditions, adduce ample evidence to show that the alkaloid quinine can hæmolyse red blood cells, but that a direct action of the alkaloid in the body is excluded, because the concentration of the quinine in the blood plasma of persons under treatment for malaria is utterly insufficient to produce an ascertainable amount of hæmolysis.

Since quinine plays a part in producing this peculiar condition, but does not cause it directly, it was necessary to look farther afield for other ætiological factors. The authors have investigated the condition of the plasma itself, since in another disease, in which dissolved blood corpuscles are seen, the hæmolysis has been proved to be due to a substance in the serum known as hæmolysin. No trace of such a substance could be found in the serum of blackwater-fever patients. They leave this riddle unsolved, and turn to the question of the situation in which the hæmoglobin is set free. Proof appears to have been found that the site is the blood itself, and not the kidneys or urine, as had been supposed. Another fact which has been brought to light by the authors is that the only change which occurs in the kidneys in uncomplicated cases of the fever is the appearance of a brownish material placed in the lumen of the renal tubules. No degeneration or other indications of pathological conditions are to be found.

Various other points are dealt with, and the reading of the work is materially assisted by the publication of summaries at the termination of each chapter. The theoretical reasoning is well carried out, and the work, while failing to solve a difficult problem, certainly illuminates many contributory factors in the production of blackwater fever.

H. W. ARMIT.

THE ORGANISATION OF TECHNICAL EDUCATION.²

THE position of higher education has altered immensely in the last ten years since I ceased to be intimately connected with teaching. In the first place, the number of agencies engaged in the work has multiplied, the number of students they attract has grown, and the funds at their disposal are greatly larger. At that time there were two universities in England, besides the old foundations of Oxford, Cambridge, and Durham—London University, a purely examining body, and the Victoria University at Manchester, uniting the three colleges in Manchester, Liverpool, and Leeds. Now, if we may reckon Newcastle in addition to Durham, there are seven, each well equipped, and with a staff of professors competent and anxious to advance knowledge and to train their students for the duties of life.

But, besides this, there is in almost every important town a technical school or college supported by municipal funds, in two cases at least outside London an integral part of the university, everywhere doing work which must be done if we are to maintain our position in the world.

¹ "An Investigation into the Mechanism of Production of Blackwater." By Dr. J. O. Wakelin Barratt and Dr. Warrington Yorke. (Being the Report of the Blackwater Fever Expedition to Nyasaland of the Liverpool School of Tropical Medicine, 1907-9.) *Annals of Tropical Medicine and Parasitology*, series T.M., vol. iii., No. 1, October. Pp. 256; with numerous illustrations and tables, &c. (Liverpool: University Press; London: Constable and Co., Ltd., 1909.) Price 10s. 6d.

² From the presidential address delivered to the Association of Technical Institutions on February 11 by Dr. R. T. Glazebrook, F.R.S.

I do not mean that these technical colleges are all new since 1899; most of them, possibly all, were in existence before that time, but their importance is now more fully realised, and the magnitude of their task more completely grasped, by those who are responsible for their maintenance and progress.

Turning to London, we have the University with its colleges, University College, King's College, and the East London College, struggling to realise under no small difficulties the ideal of a great teaching university, and doing it with increasing success; the Imperial Technical College, with its constituent parts; the Royal College of Science; the Royal School of Mines; and the City and Guilds College, which has just started with high aims on its difficult task; and the numerous technical colleges too many to mention, some of them old institutions inspired to new endeavours by the wise action of the Charity Commissioners, the generosity of city companies, the vivifying influence of the whisky money, or the foresight of the education authority for the county.

A list containing the names of these institutions throughout the country, showing the funds administered on their behalf, their staff of teachers, and their roll of students, would prove a formidable document, and if the list were compared with a similar one drawn up ten or fifteen years ago the amount of progress would be obvious. I am aware, of course, that if we compared it with a similar list drawn up for Germany or America, our numbers and resources would appear but small.

I do not direct attention to our growth in any spirit of self-glorification or with any view to suggest that we ought to be satisfied, but rather that you who are so well qualified to advise and to judge may take stock of the position, may ask yourselves whether your efforts are in all cases being well and wisely directed, what ought to be your aims, and what your own position relative to the other agencies around which have the same general object in view.

This is, I take it, the more necessary because of the probable large influx of additional work with which in the course of a few years educational authorities in all parts of the country will probably be called upon to deal, while here in London the need for some general consideration is the more urgent because of the work which the Royal Commissioners for the University of London are now engaged upon.

What are the aims which we whose work lies mainly with the technical institutions of the country have to set before ourselves? What is our position in the scheme of education which is gradually being evolved?

Now there are two sets of individuals, for each of which a somewhat different course of training is needed, those who are to be leaders in industrial pursuits and those who will ever remain among the rank and file. While it should always be possible for the workman to rise to the rank of leader—and your scheme of education must give full opportunity for this—the methods of a trade school aimed chiefly at giving to the workers in its district that fuller knowledge which makes their labour skilled must clearly differ from those of a college designed to give the highest technical training to those who are to lead and guide the workers.

M. Leduc, in a recent paper published in the *Bulletin de la Société pour l'Industrie nationale*—the Society of Arts of France—directs attention to the four-fold division of German instruction in technological science:—

- (1) The comprehensive training which is to turn out the future captains and leaders of industry.
- (2) The provision for putting trustworthy information on technological matters at the disposal of traders.
- (3) Central institutions established for the scientific and practical study of special industries, and
- (4) Local technical schools adapted to the special needs of particular localities.

In Germany, as we know, the great technical institutions have developed almost independently of the ancient universities.

The term university was, we are told, in the Middle Ages used to denote any community or corporation regarded under its collective aspect, but finally it came to mean a community of teachers and scholars whose corporate existence had been recognised and sanctioned by civil or

by ecclesiastical authority, or by both. In its earliest stage it was probably a scholastic guild, a spontaneous combination of teachers and scholars formed on the model of the trades guilds or guilds of aliens, in great measure for mutual protection. In still earlier days learning flourished mainly, if not entirely, in the monasteries and cloisters, and the earlier universities took their rise in the endeavour to provide instruction beyond the range of the monastic schools. For the most part they were organised under the four faculties of theology, law, medicine and philosophy, or the arts, and they retained this constitution until the last century.

In Germany the activity and importance of the universities dates from the time after Jena, 1806, when, as we were reminded by Sir Norman Lockyer in his presidential address to the British Association in 1903, King Frederick William III. and his counsellors, among them Wilhelm von Humboldt, founded the University of Berlin "to supply the loss of territory by intellectual effort." In the main, however, it was founded on the ancient lines, and when later on in the century the problems of the application of science to industry had to be faced, and the technical high schools came into existence, they were developed independently of the universities.

By 1903 the separation from the universities had become definite. In Prussia the Emperor had recognised it by giving certain of the great schools the right to grant the degree of Doctor of Engineering, thus putting them on an equality with the universities, and by admitting the principals to the Prussian House of Lords, giving them the title of His Magnificence.

Now there are in Germany ten of these technical universities, at Dantzig, Berlin (Charlottenburg), Aix, Hanover, Munich, Karlsruhe, Dresden, Stuttgart, Darmstadt, and Brunswick, all over the length and breadth of the land, with nearly 12,000 fully qualified day students between them, and more than 2000 in addition whose qualifications are not complete. Last year 1668 diplomas were granted, and of those who received the diploma 130 took the degree of Doctor of Engineering.

The age at which these students begin their work is from eighteen to nineteen years, and the "matriculation for fully qualified students at German technical universities is the completion of the full nine years' secondary-school course at a classical, semi-classical, or modern secondary school." Besides these, there are the twenty older universities, with 48,000 students, of which a large number study chemistry and, to use a Cambridge official phrase, "other branches of physics." The students work for four years, usually after a minimum period of one year in works, and the aim of the institutions is to train experts, inventors, high technical State and municipal officials, captains of industry, owners of great works, professors, secondary teachers, engineers, architects, chemists, &c.

Besides these ten technical universities, there are special engineering and other technical schools for the training of owners and managers of small works, foremen, clerks of works, surveyors, draughtsmen, and the like.

Now I have not referred to this merely to mark our own deficiencies, but rather to afford some guidance as to the lines along which we are to develop. Are we to look forward to the growth of technical universities in each town arising naturally out of the colleges with which we are connected, but independent of, and at the same time rivals of, the universities which in many cases exist already alongside our own colleges?

The answer to this question must, I think, be in the negative, with possibly one or two exceptions—we will put aside, for the present, London and the two ancient universities—it would, I think, be suicidal to suggest that in Manchester or Birmingham, Leeds or Liverpool, there should be two degree-giving bodies, one connected with the arts, literature, and pure science, the other with those applications of science on which industry depends; and for this reason, among others. The universities of England are modern creations animated by modern ideas, and controlled by men whose main endeavour is to bring home to the mass of their countrymen the blessings of knowledge. The seclusion of the mediæval cloister, the quiet of the monastery, or even of the courts and quadrangles by the Isis and the Cam are not for them. They are

placed amid the busy haunts of commerce; close to the foundry and the workshop, and their students seek to draw from ancient learning and from modern research alike those lessons of truth, those unerring laws of nature in accordance with which we must progress if our country is to remain great, to hold the premier place among the nations.

These universities will do for us what the technical high schools have done for Germany.

Let me note one important difference between their constitution and that of the ancient universities. They are not Republics; the Senate, the general body of professors and independent lecturers, is not the governing body. The court, with which control ultimately rests, is a large body representing all interests in the town and district. The court selects the council, which has executive power, and on both bodies the teachers have representatives; but in this way the effective management of the university is in the hands of a small body of business men ready to give the fullest attention to the wishes of the teachers, but capable of bringing other qualities to the consideration of the complex problems with which they have to deal, experienced in dealing with men and with affairs.

The prospects of the modern universities of England are bright; it is our business in our technical schools to supplement by all means in our power the efforts they are making to solve a difficult problem. Those who are to speak to-morrow can tell you better than I how the task is being done.

But with all the progress we have made we are still far behind Germany in very many vital respects. I am aware that the standard of entrance at our universities is being gradually raised; it will be long indeed before it reaches the nine years' secondary-school course required in Prussia for admission to any of its four technical universities. Still, we may look forward with some certainty to the time when our universities will do the work for England that those four universities do for Prussia; and while in some cases the connection between the technical college and the university will be very close, it is well to realise that there is an immense task before us which cannot be touched by the universities. University work is, in the main, day work; it calls for the whole time, the whole energy of the student; it may be that for a time, in some of its preliminary stages, some progress can be made by evening work, but a full university course demands more time than a hard-worked man should give after his day's task is done. The marked feature of the technical college is its evening work, the education it provides for those who have by day to make their living, raising and improving the quality of their work by training their intelligences, by putting clearly before them the why and the wherefore of the processes in which they take part.

I am not sure whether statistics exist as to the number of these students, the classes they attend, and the work they do. I have seen figures for London, and no doubt they might be obtained for the country at large. Few among these students hope to reach university standard, nor should their teaching be planned as though this were the main object in view. They fall, it seems to me, into two main categories, the adolescents—to use the word of the continuation schools report—who have recently left school to commence some trade, and for whom the continuation schools are designed, and then the older workmen, who want to understand the work they do, to prepare themselves for posts as foremen or overseers, and to be given some wider outlook on life than the shop or factory affords. There is room for a large development of both these tasks, for more coordination of the work, and greater continuity of effort. Elementary technical education is needed in all our towns, technical universities are needed in a few great cities only; for these latter we must concentrate both students and teachers.

A scheme whereby the evening technical institutions of a district would look to a technical university in one of the main centres of population as their university, would organise their work in connection with the day classes of the university, and would confine their own ambitions within moderate bounds, endeavouring to do their work within those bounds with the highest possible efficiency, would do much for the real interests of the nation. To promote such a scheme ought not to be a task beyond

the powers of this association. It is a national work, and one which should readily gain the assistance of the national authorities.

In any scheme two matters must be borne in mind. A system of bursaries and scholarships must open the university to any student who can sufficiently profit by the opportunity thus offered; this is generally admitted; but, in addition, it should be possible for the teachers to advance knowledge by research and study. To do this in each technical school or trade school is clearly impossible. If its importance were once recognised, it ought to be possible to arrange for facilities for the work for teachers in the district in the laboratories and class-rooms of the university.

Oxford and Cambridge are outside any such scheme. London, again, offers special problems of its own.

The two ancient universities need not detain us long. England owes so much to them, and English science so much to Cambridge in particular, the home of Newton, Young, Cayley, Stokes, Kelvin, and Maxwell, to name mathematicians alone, that one who realises all the benefits Cambridge can bestow upon her sons can only express the very deepest regret that the regulations of the University still close her doors to many young Englishmen on whose future she could exert an inestimable influence for good; still, even if an elementary knowledge of Greek were no longer necessary for entrance, Cambridge must devote herself rather to the study of pure science than to that of technics and engineering; students who go to Cambridge are prepared to spend time and money in gaining other advantages besides those of their technical education. Cambridge does not aim at being one of the great technical universities, but rather a home of sound learning and religious education from whence may spring great generalisations and new ideas to fertilise the world.

As to London, the problem is most complex. We have the university, the university colleges, now happily a part of the university itself, the Imperial Technical College with its own constituent parts, the Royal College of Science, the Royal School of Mines and the City and Guilds College, the Finsbury Technical College, and the various polytechnics and trade schools. What, from our point of view, are to be their connections; and under what scheme can they best combine to meet the wants of the seven millions of people for whom they provide?

We have to provide for the masters and leaders of industry by institutions giving a wide and comprehensive training suited to their needs; we have to secure that the workers shall be able to gain the knowledge needed to make their labour fruitful to themselves and to the State; when young in technical schools adapted to the requirements of their trade, and when more mature in more highly specialised institutions organised to promote the scientific and practical study of special industries.

There is yet another class, limited in numbers, but valuable beyond measure to the State, those to whom it is given to advance learning—the potential Faradays of this great city.

For the first class we have the university, with its constituent colleges and parts; but are we to have one university or two? Shall London University embrace, as its name would imply, the whole of learning, the arts and sciences, literature, economics, theology, law, medicine, and the technical applications of science, or are we, like Berlin, to have two universities side by side, the one dealing with the older studies and pure science, the other the technical university, taking under its care those practical developments of science on which the welfare, nay, the very life, of the country hangs?

The matter is now under consideration, and this is, perhaps, hardly the place to discuss it. I would only say that the example set by Germany, though to follow it would entail many difficulties, is not lightly to be set aside. In any case, some change must come in the present government of the university—a change, I trust, which will place the executive control of its fortunes in the hands of a much smaller body than the Senate, will leave the various faculties more free to develop on the lines best suited to each case, and will concentrate more completely than is at present possible the highest studies,

affording to its students the opportunities which they now lack for post-graduate study and original research.

At any rate, we may take it that the Imperial Technical College will become the technical university for London—whether as a part of London University or as a new university working alongside it does not for our present purpose matter—concerned chiefly with honours students entering with high qualifications for a three or four years' course, including post-graduate study and research.

While referring to research, let me say I do not think you can successfully command a college, either by Act of Parliament or by Royal Charter, to become the home of original research. You can foster the endeavour by your regulations and the proper provision of funds, but success depends mainly on the men who guide the students and direct their energies. It was Liebig who made Giessen; the physical laboratory of Berlin became famous because Helmholtz worked there; it was not the cellar in the old university buildings, or the funds available for inquiry, which drew students from all over the world to Kelvin's laboratory at Glasgow. Rowland and his staff are the real founders of the Johns Hopkins University; to-day it is Thomson who fills the Cavendish Laboratory and Ramsay who attracts our ablest chemists to a somewhat second-rate laboratory in Gower Street. To expect a distinguished body of post-graduate students to flock at once to a newly opened college is a vain hope; but this is a digression. The Imperial Technical College will in time become the technical university of London. To achieve all that is aimed at, time and a more generous support on the part of those who have interests of education at heart alone are needed.

To this university there must be many avenues of approach; it must spread its roots afield; among its students some—by no means all—will pass through the polytechnics, for it appears to me the primary work of the polytechnics is not to prepare undergraduates for degrees in science and engineering, but rather, in the first instance, to supply needful knowledge to the worker.

No doubt it is necessary that, in view of the size of London, there should be centres of university work in various parts; it is desirable that some of the polytechnics should organise themselves so as to meet this demand; but is it necessary for all to do so? I do not wish to express an opinion so much as to raise a question.

I think I realise in part the feelings of the teachers; their university students are, I take it, among their best; the chance of doing research work turns largely on having one or two such students, and research work must be done if your teaching is to be kept alive and your courses, at any rate to advanced students, made fruitful; but is the highest work, or even work up to degree standard in many subjects, to be attempted in every polytechnic? The expense of such a plan must be very heavy, the strain on the teachers enormous. Suppose that, instead of endeavouring to cover all the instruction required for the B.Sc. degree, each institution made a serious effort to specialise only in one or two of the required subjects, leaving the others to other polytechnics, would not this relieve the pressure? In this chosen subject the principal would draw round him a large and able staff who would attract students from a wide area, and his college might in time become a specialised school of technical research. The teachers in this subject would find in their work ample opportunities for investigations of real importance; in the other branches of science the work would be avowedly more elementary, and the teachers probably less competent to research; but if the classes were mainly evening, such of the staff as wished might carry on investigation in the central laboratories of the university, or possibly at some other polytechnic where the subject of the research was made a special object of study.

One point more. Among your many students are some of very marked ability, perhaps of genius. Ease their paths by all methods within your power. Let me urge on the governors of your various institutions, and on those who hold the purse, if there are any such who can hear me, that expenditure on scholarships or bursaries for such, on material and apparatus for their researches, will soon repay itself in the effect their work will have in applying science to industry and trade, in discovering new means

whereby the forces of nature may be harnessed to do the work required by man.

To conclude; my dream would picture a central technical university for London, a place where students only of proved capacity were admitted, where the staff were free to conduct original investigations and through these to teach their students, where scholars and prizemen from the various technical institutions of the district were collected; and where the teachers in the polytechnics and other colleges were freely welcomed to carry out researches.

In close connection with this there would be a number of colleges, day colleges chiefly, organised so as to provide the teaching required for the less advanced stages of the university. The suitable centres for this work would, of course, need to be selected with due regard to geographical conditions. Beyond these, again, would come the polytechnics, engaged chiefly in evening classes for the worker, but each with its one or more departments organised so as to provide teaching and means for research of the highest character, with its teachers recognised by the university, having a common interest in promoting the welfare of the central body and looking to the professors as their leaders in the search for truth.

Whether this dream comes true or not, I am clear that a scheme for technical education in London must aim at coordinating existing effort round a central institution; and in this endeavour must recognise the self-sacrificing labours of those who, in the past ten years, have done so much to forward the great movement—the governors and the staff of the institutions represented on this association.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The general board of studies will shortly proceed to the appointment of a Stokes lecturer in mathematics, in succession to Prof. Hobson. The appointment will be from June 24, 1910, to September 29, 1913. The annual stipend is 200l. Candidates are requested to send their applications, with a statement as to the branches of mathematics on which they are prepared to lecture, and with testimonials if they think fit, to the Vice-Chancellor on or before April 25.

The Allen scholarship has been awarded to Mr. R. Whiddington, of St. John's College. Mr. Whiddington took a first class in physics in part ii. of the natural sciences tripos in 1908.

SIR ALFRED KEOGH, K.C.B., formerly Director-General of the Army Medical Service, has accepted the rectorship of the Imperial College of Science and Technology, and will take up his work at an early date.

A REUTER message from Bombay announces that Sir Carrimbhoy Ebrahim has given to the Bombay Government a sum of 30,000l. for the improvement of scientific training, the encouragement of research, and the provision of scholarships to science students of the Mussulman faith.

A MEETING of the London branch of the Mathematical Association will be held at the L.C.C. Training College, Southampton Row, W.C., on Saturday, March 19, at 2.30 p.m. Papers will be read on the teaching of graphs, by Dr. T. Percy Nunn and Mr. P. Abbott. A discussion will follow, which will be initiated by Mr. D. Mair. All who are interested in the work of the association are invited to attend.

THE Fresenius Chemical Laboratory, Wiesbaden, offers opportunities for the pursuit of study and research in chemical science in an attractive part of Germany. The directors of the institution are Prof. H. Fresenius, Prof. W. Fresenius, and Prof. E. Hintz, and there is a large staff of lecturers and assistants. The summer term will begin on April 25, and among the subjects of lectures announced are chemical technology, stoichiometry, microscopy and chemistry, and analysis of foods. Copies of the regulations and the syllabus of lectures may be obtained upon application to one of the directors of the laboratory.

THE Old Students' Association of the Royal College of Science, London, has commenced the publication of a *Record*, which is to be issued at irregular intervals as

occasion may demand, containing information in regard to the work of the association and other matters of interest to old students. The association has accomplished some useful work during the first year of its existence. A register containing particulars of 729 old students has been published, steps are being taken with a view to secure academic costume for associates of the college, and inquiries are being made with the intention of offering evidence before the Royal Commission on University Education in London. We notice that Sir Thomas Holland, K.C.I.E., F.R.S., is the president of the association for the current year.

MR. F. M. DENTON, of the Carnegie Technical Schools, Pittsburgh, has been appointed to the post of associate-head of the electrical engineering and applied physics department of the Northampton Polytechnic Institute, Clerkenwell, London, E.C., tendered vacant by the resignation of Dr. C. V. Drysdale. Mr. Denton received his technical training at the Central Technical College of the City and Guilds of London Institute, and for a time he occupied a position on the staff of the electrical engineering department of the college. He left to join the staff of the General Electric Company in various departments at Pittsfield, Mass., and at Schenectady. After occupying these positions for one year he was, two and a half years ago, appointed lecturer in electrical engineering at the new Carnegie Technical Schools at Pittsburgh, a position which he still occupies and is resigning to take up his London appointment.

THE Department of Agriculture and Technical Instruction in Ireland has distributed a circular (Form S 41) giving full particulars of its summer courses of instruction for teachers, to be held, for the most part, in Dublin during July and August next. In July, courses will be conducted by the Department in, among other subjects, experimental science, laboratory arts, and drawing and modelling for teachers in day secondary schools, and in day and evening science and art classes; in domestic economy and woodwork for teachers in day secondary schools; and in hygiene and sick nursing and in housewifery for domestic economy instructresses. For August, four courses have been arranged, as follows:—in metalwork, practical mathematics and mechanics, and in hand-railing, for teachers of wood-working; in industrial chemistry for teachers of chemistry in technical schools; in rural economy for teachers of experimental science in technical schools and teachers in national schools; and in school gardening for teachers in schools with gardens. The syllabuses of work contained in the circular show that great pains have been taken to provide practical courses dealing with subjects which will be directly useful to teachers in their work, and they should also serve the purpose of adding new life to their lessons when the teachers return to their schools.

ON Friday, March 11, Sir William H. White, K.C.B., F.R.S., distributed the certificates and prizes at the South-western Polytechnic Institute, Chelsea. Mr. W. Hayes Fisher, M.P., occupied the chair. After the principal had read the report for the session 1908-9, and the certificates had been distributed, Sir William said that in education he has three articles of faith, namely:—(1) every child should have an opportunity for education; (2) all who give proof of capacity of profiting by higher training must be allowed to go on; (3) in getting the best educational results the natural process of gradual selection must be adopted and allowed to operate. This leads to apparent wastage; but there is no real wastage. It is necessary to have educated men of all grades in all works, and this has specially to be brought home to the English manufacturer, who does not yet realise the importance of higher education. Sir William said that in Chelsea he felt at home, for when he came from Devonshire, before he joined the Admiralty in 1867, he studied at the School of Practical Shipbuilding at South Kensington, and lodged on King's Parade, Chelsea, almost within a stone's throw of the polytechnic. He was very pleased with his inspection of the polytechnic last week, and specially congratulated the governors on the large amount of their day work. From his experience of the technical colleges and institutes in London he had come to the conclusion that

the polytechnics must be encouraged to carry on and extend day courses—their work in the evening was without parallel in the educational world. Various subjects must not be concentrated in special buildings, but each institute should make its courses as wide and as general as possible. London was so extensive, and its population was so large, that there was an ample field.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, March 10.—Sir Archibald Geikie, K.C.B., president, in the chair.—C. Gordon Douglas and Dr. J. S. Haldane: The causes of the absorption of oxygen by the lungs (preliminary). A short preliminary account is given of experiments affording clear evidence of a secretory activity of the lungs in the absorption of oxygen.—V. H. Vello and A. D. Waller: The action of nicotine and other pyridine bases upon muscle, and on the antagonism of nicotine by curarine. Nicotine (mol. wt.=162) as such, or in the form of salt as nicotine tartrate, produces a very characteristic effect upon the contraction of isolated muscle. Its toxic power upon muscle, as compared with that of other substances that the authors have dealt with, is of the following order, i.e. approximately one-third that of quinine and considerably greater than that of curarine:—

Aconitine ...	...	...	...	10,000
Quinine ...	...	...	...	100
Nicotine ...	...	...	...	33
Strychnine ...	...	...	...	12
Curarine ...	...	...	...	5

The effect on muscle, characteristic of nicotine, is not produced by its parent base pyridine, nor by picoline, nor by piperidine. The order of toxicity upon muscle of these substances as compared with that of nicotine is as follows:—

Nicotine ...	...	...	...	100
Piperidine ...	...	...	...	50
Pyridine ...	...	...	...	10
Picoline ...	...	...	...	10

As has been indicated by Langley, there is an antagonism between nicotine and curare. Using a solution of pure curarine iodide prepared by Prof. Boehm, we find that the characteristic effect of nicotine upon muscle is abolished when the proportion of curarine to nicotine, reckoned by molecules, is 2 to 1, 30 to 1, and 160 to 1. With this last proportion a trace of nicotine effect can still be detected. In the case of other poisons, viz. strychnine, quinine, and aconitine, of which the effect *per se* upon muscle considerably exceeds that of curarine, there is, in a sense, an antagonism, as shown by abolition of the characteristic nicotine effect, but the abolition requires a greater mass of these more powerful poisons than is sufficient in the case of the less powerful poison—curarine. Thus, approximately, whereas 1 mol. of curarine can overpower upwards of 100 mols. of nicotine, it requires 1 mol. of strychnine or of quinine to overpower 1 mol. of nicotine, and 1 mol. of aconitine can overpower at most 10 mols. of nicotine. But in these cases the result appears to the authors to be intelligible as an effect of subdivision of muscle stuff between two poisons similar to the case of the subdivision of an acid between two bases; but this explanation is hardly applicable to the case of the antagonism of the strong poison nicotine by the weak poison curarine.—Prof. H. E. Armstrong and E. H. Horton: Studies on enzyme action, xiii., enzymes of the emulsin type.—Miss M. P. Fitzgerald: Preliminary note on the origin of the hydrochloric acid in the gastric tubules.—C. J. T. Sewell: The extinction of sound in a viscous atmosphere by small obstacles of cylindrical and spherical form. The results obtained in this paper are only valid when the dimensions of the obstacles are small compared with the wave-length of the incident sound. For cylinders and spheres the radius of which is not less than 10^{-3} cm. it is found that the ratio of the lost energy to that incident upon the obstacle is at most of order 10^{-3} ; this is a very much larger proportion than is obtained in the case of a non-viscous air. The results obtained for a single obstacle are extended without difficulty to the case of a large number

of obstacles. This extension is valid only when the space occupied by the obstacles is small compared with the total volume. It appears in the case of spherical obstacles that, if each small obstacle has radius 10^{-2} cm., and there are 10^6 of them per cubic centimetre, then sound of wavelength 50 cm. will have its intensity diminished in the ratio of $1/e$ after passing through a thickness of less than 12 cm. of such a medium.—Dr. R. D. Kleeman: The ionisation of various gases by the β rays of actinium. A set of experiments carried out on the ionisation in various gases by the β rays of actinium. The results are of interest in comparison with the ionisations produced by the β rays of uranium, on account of the different penetrating powers of the rays. The results are exhibited in the subjoined tables. It will be seen that the relative ionisations by the β rays of actinium are practically the same as those obtained with the β rays of uranium.

Scattering of β Rays.

Absorbing substance	β Rays of actinium (Godlewski)	β Rays of uranium (Rutherford)
Aluminium	32.7	14
Mica	33	17.2
Brass	108	—
Copper	139	60
Tinfoil	154	—
Lead	163	122

Relative Ionisations.

Vapour	β Rays of actinium	β Rays of uranium
Air	1.00	1.00
H ₂	0.159	0.165
C ₂ H ₁₀ O	4.28	4.39
C ₂ H ₅ Cl	3.33	3.24
C ₂ H ₅ Br	4.43	4.41
CH ₃ F	5.34	5.11

Geological Society, February 18.—Annual general meeting.—Prof. W. J. Sollas, F.R.S., president, in the chair.—Prof. W. J. Sollas: Anniversary address: the evolution of man in the light of recent investigations. Considering first the human remains of the Pleistocene epoch, the president pointed out that, so far as the evidence extends, it shows that the cranial capacity of the human skull increases rather than decreases as we pass backwards in time. The oldest known human skulls are later than the Chalky Boulder-clay. The cranial capacity is merely a morphological character of unknown significance. Observation shows that no discoverable connection exists between it and the intellectual power. The most recent researches in comparative anatomy emphasise the close connection between man and the anthropoid apes, especially the gorilla and the chimpanzee. A similar result is afforded by the investigations of Uhlenhuth and Nuttall into blood-relationship. All recent researches converge to show that the genealogy of man is to be traced through the anthropoid apes and the catarrhine monkeys to the lemurs. Cope's suggestion of a direct descent from extinct lemurs receives no confirmation. Primitive characters, when present in man, can be better explained by regression and adaptation. Man probably diverged from the phylum of the primates above the point of origin of the gibbon, and not far from that of the gorilla and the chimpanzee. He owed his progress, in the first place, to emancipation from a forest life, and commenced his career as the ape of the plains. The erect attitude and the use of the hand as a universal instrument followed as a consequence. Ancestral man was probably a social animal at a very early period, and social life afforded a stimulus to the development of the powers of speech. He was probably distinguished by great bodily strength and by the possession of formidable natural weapons of defence and offence. With the invention of weapons made by art the necessity for natural weapons disappeared, and a regressive development of the teeth with adaptation to purely alimentary functions commenced. A purely human dentition characterises the Heidelberg jaw, which is the oldest known. This, however, still reveals in all other respects strong simian affinities. The growth of the brain in size and complexity might be correlated with the evolution and use of the hand, but to a far greater extent with the development of

the powers of speech and the consequent exchange, multiplication, and coordination of ideas.

February 23.—Prof. W. W. Watts, F.R.S., president, in the chair.—T. O. Bosworth: Metamorphism around the Ross of Mull granite. The Ross of Mull granite is a coarsely crystalline plutonic mass, forming the western portion of the Ross of Mull, and extending over some twenty square miles. The intrusion is conspicuously later than the Moine rocks, and is regarded as one of the "newer granites." The rock shows very little evidence of faulting or movement of any kind, and is traversed by sheets of mica-trap. The eastern boundary of the granite is a very intricate line of junction with typical Moine schists and gneisses, into which it has been intruded. Injection-breccias occur along the margin, where the granite is crowded with schist-inclusions. The changes in the pelitic schists are of two kinds, and are considered under the separate headings (a) impregnation, and (b) thermal metamorphism.

Zoological Society, March 1.—Dr. A. Smith Woodward, F.R.S., vice-president, in the chair.—Sir G. F. Hampson: A list of the moths collected by Mr. Sheffield A. Neave in Rhodesia north of the Zambezi and the adjacent Katanga district of the Congo Free State. Nearly two hundred new species are described. The moth fauna of the district is mainly of a West African type, with a considerable admixture of East African and Mashonaland forms. As there are no high ranges of mountains or deep river valleys, the fauna presents a very uniform tropical African character, with no high mountain forms or forms peculiar to the faunas of the drier parts of southern or northern Africa.—T. H. Burlend: The urogenital organs of *Chimaera monstrosa*. This paper dealt with the urogenital organs of *Chimaera*, both immature and adult of each sex. Much of the early work of Leydig and Hyrtl, which later writers had ignored or disputed, was now confirmed and supplemented.

Royal Anthropological Institute, March 8.—Sir Herbert Risley, president, in the chair.—Dr. A. Keith: The Gibraltar skull. This skull was presented to the Museum of the Royal College of Surgeons, England, some forty years ago by Mr. Edward Busk. Huxley had seen the cranium, but evidently did not recognise that it was of the same type as the Neanderthal skull. The merit of discovering that this skull was Neanderthaloid and belonged to that ancient Palaeolithic race of men to which Schwalbe has given the specific name of *Homo primigenius* belongs to several anthropologists, but to Prof. Sollas must be ascribed the merit of having given, quite recently in the Philosophical Transactions, the first detailed description. The skull deserved further investigation, because it was the only specimen of Neanderthaloid man yet known that showed the face in a perfect condition. In the two recently discovered examples described by M. Marcellin Boule and by Prof. Klaatsch, the facial parts were so mutilated that reconstruction was necessary to obtain an approximate conception of the original or natural form. Dr. Keith, with the aid of Mr. F. O. Barlow, had been able to obtain a cast of the interior of the skull, and was thus able to study certain surface markings of the brain. The brain-cast was remarkable for its width and for its flatness; the left occipital pole predominated over the right occipital pole, a character that has been associated with right-handedness. The fissure of Sylvius was wide and apparently open, but this character is due, as in native Australian brains, to the great size of the ridge of bone which occupies the fissure. It has been found possible to expose the sutures of the Gibraltar skull, and thus to localise definitely important points in its topography. The cerebral development of Palaeolithic man has been very much underestimated. This is partly due to the fact that the height of the skull was measured from theinion to the glabella, two points which are fairly stationary in modern men, but which in Palaeolithic men, as in anthropoids, grew upwards so as to occupy a relatively high position as regards the brain. These points are from 8 to 10 mm. higher in Palaeolithic men; hence the height of the skull, when measured from them, is comparatively low. M. Boule has found the capacity of the La Chapelle skull to be considerably above the average for modern Europeans, and such was undoubtedly the case as regards

the Neanderthal and Spy crania. In the Gibraltar skull the capacity was low, below 1100 c.c., a small amount, partly owing to the skull probably being that of a woman and also to the fact that it was pre-Neanderthaloid in type. Indeed, when rightly analysed, the Gibraltar individual, as regards the type of cranium and size of brain, is intermediate between *Pithecanthropus* and Palæolithic skulls, such as those of the La Chapelle man or the skull known as *Spy* II. The mastoid of the Gibraltar skull is simian in type; the groove for the attachment of the digastric muscle is exposed laterally, as in the anthropoids, in place of being covered by the mastoid processes. Palæolithic men were distinguished by the width of the attachment of the skull to the neck, as well as by the simian supraorbital ridges. The nose of the Gibraltar individual is unlike anything yet seen in a human being. Although in certain features it shows approximation to the gorilla, it is best described as the precursor of the prominent European nose. The jaw is remarkable for its width; in length it does not much exceed that of a modern European. The third molar is larger than the second, at least one so infers from the parts that still remain. This shows a very robust dental development. It is evident that Palæolithic man had reached quite a modern degree of brain development. If the Gibraltar individual be assigned to a Palæolithic date, for we can assign its period only from its conformation, there being no accessory data, then it must be assigned to a woman of a much lower brain development than the men now assigned to that period; but it is also possible that it belonged to a much earlier date than the Neanderthal-Spy men—to a race we know nothing of as yet. Dr. Keith also pointed out that in the pathological condition, known as acromegaly, the eyebrow ridges and attachment of the skull to the neck became enormously increased, thus reproducing a character which was normal in Palæolithic men. It seemed very probable that racial characters were determined by secretions of the more obscure glandular organs of the body, especially the sexual glands.

Mathematical Society, March 10.—Sir W. D. Niven, president, in the chair.—J. W. Nicholson: The scattering of light by a large conducting sphere.—Miss H. P. Hudson: The 3-3 birational space transformation.—W. F. Sheppard: The expression of the sum of the n th powers of the first n natural numbers and other similar functions of n in terms of $n+1$, and forms for the remainder in the Euler-Maclaurin sum-formula.

Linnean Society, March 3.—Mr. H. W. Monckton, treasurer and vice-president, in the chair.—W. Bickerton: Our British nesting terns.

Academy of Sciences, February 28.—M. Émile Picard in the chair.—Émile Picard: A general theorem of certain integral equations of the third species.—J. Boussinesq: The manner in which the potential of the velocities depends upon the initial state in the problem of waves by emersion.—A. Haller and A. Brochet: The oxidation of methyl ricinoleate by ozone. The ester fixes four atoms of oxygen on treatment with ozonised oxygen. The separation of the products formed by the interaction of this substance with sodium carbonate is described in detail; the position of the double linkage thus determined is in agreement with the constitution usually ascribed to this acid.—M. Lannelongue: A supplementary function of the foot in the yellow race. The foot in these races is not exclusively used for the support of the body. It is used for other functions, and becomes a prehensile organ, as in grasping an ear.—Émile Borel: A general condition of integrability.—Émile Cotton: Asymptotic solutions of differential equations.—Serge Bernstein: The conditions necessary and sufficient for the possibility of the problem of Dirichlet.—Joseph Marty: An integral equation.—Léopold Fejér: A pair of conjugated Fourier's series.—J. B. Fournier: A method of evaluating the temperature of superheated vapour. Superheated steam differs from saturated steam in that adjacent portions may have very different temperatures, and this fact has not been sufficiently appreciated in many instances when fixing the position of the thermometer designed to give the temperature

of the superheated vapour. The error may amount to as much as 75°. The whole of the bulb, or corresponding portion of an electrical instrument, must be entirely immersed in the direct current of vapour, and contact with the walls of the pipe must be avoided.—Ch. Féry: A symmetrical coil for galvanometers with movable frame.—G. Gabet: The results obtained in the radio-automatic torpedo by a new telecommutator. The principles upon which the apparatus is based were given in a previous communication. Practical tests in the Seine have been successfully carried out.—E. Louise: A new method of analysis by miscibility curves. Application to essence of turpentine. Aniline is a suitable solvent for this work, four curves obtained with this substance being illustrated.—E. Baud: Cryoscopy in concentrated solutions. The concentration is taken as the weight of the solute dissolved in a given volume (100 c.c.) of the solution, a non-polymerised solvent being used. Results are given for ethylene bromide, benzene, and nitro-benzene as solvents.—G. Denigès: The detection of traces of formaldehyde in presence of acetaldehyde by fuchsine bisulphite. In liquids acid with sulphuric acid the red colour restored to the decolorised fuchsine solution by the acetaldehyde is much less stable than that produced by formaldehyde. The latter tends to increase on standing, the former to fade away.—F. Bodroux and F. Taboury: Syntheses effected with benzyl cyanide. Nitriles in ethereal solution react readily with sodium amide, giving sodium derivatives of the type $R.CH.Na.CN$. The latter can be converted into compounds $R.CHR'.CN$ by alkyl halides. Several examples of the application of the reaction are given.—J. Bougault: α -Cyclogeranic acid. The acetate of trimethylcyclohexenol is obtained in good yield by heating α -cyclogeranic acid with an acetic acid solution of mercuric acetate.—Marcel Delépine: The constitution of the dimeric aldehyde of crotonaldehyde.—A. Wahl and C. Silberzweig: The methyl methoxybenzoylacetates. The methyl esters, differing from the ethyl esters, can be distilled undecomposed in a vacuum. These compounds were prepared by Claisen's method. Details of the preparation and properties of these compounds are given.—A. Backe: A new compound contained in food products. The reactions of this substance are sufficiently close to those of salicylic acid to give rise to the suspicion that the latter substance has been added. This body is formed by the action of heat on certain sugar and starches, and resembles the maltol of Killiani and Barlen.—Louis Matruchot: A new group of pathogenic fungi causing sporotrichosis.—G. André: The development of a bulbous plant. Variations in the weight of the dry material.—Ed. Urbain, Cl. Scal, and A. Feige: The sterilisation of water by the ultra-violet rays. The source of light employed was an arc formed between carbons containing alumina. It is pointed out that it is useless to attempt to utilise wave-lengths below 1860 Ångström units, since a thin layer of quartz or water absorbs nearly all rays of lower wave-length.—Mlle. Cernovodeanu and Victor Henri: A comparison of the photochemical and abiotic action of the ultra-violet rays.—I. Chaîne: The vertical position and the thigh muscles.—C. Vanoy and A. Conte: Researches on the development of the egg of the silkworm.—Paul Hallex: The summer and winter spawning of *Prostoma lumbricoideum*.—J. Nageotte: The microscopical study, during life, of the activity of the myelene in the course of the Wallerian degeneration of nerves.—M. Favre and Cl. Regaud: Certain filaments having probably the signification of mitochondria in the generating layer of the epidermis.—F. Bordas: The medico-legal study of the benzidine reaction in the determination of blood spots. If the reaction is negative, blood is certainly absent; it is shown, however, that a positive reaction is given by substances other than blood.—E. Doumer and G. Lemoine: Obstinate neuralgic pains observed in patients suffering from excessive arterial tension.—Jean Brunhes: The predominance of erosion on the right bank of a river in times of flood.—Alfred Angot: The secular variation of the magnetic elements in the region of Paris.

March 7.—M. Émile Picard in the chair.—Maurice Hamy: The organisation of stellar spectroscopy at the Observatory of Paris. Details are given of the new

spectrograph, specially designed for the determination of radial velocities. Special attention has been given to securing constancy of temperature, with such success that the variations during several months have amounted to two- or three-hundredths of a degree.—**J. Boussinesq**: The integration of the equations of waves of emersion by Maclaurin's formula, in series always convergent, for a deep, endless canal and for an indefinite basin.—**A. Haller** and **Ed. Bauer**: The alkylation of fatty ketones by the use of sodium amide. By successive treatments with sodium amide and methyl iodide, pinacolone was converted into $(CH_3)_3C.CO.CH_2.CH_3$, and ultimately into

In benzene solution this was further acted upon by sodium amide and methyl iodide, the symmetrical hexamethylacetone $(CH_3)_3C.CO.C(CH_3)_3$ being formed. Various derivatives of these ketones, together with the corresponding ethyl compounds, are described.—**Richard Dedekind** was elected a foreign associate.—**H. Andoyer**: New fundamental trigonometrical tables.—**J. Guillaume**: Observations of the sun made at the Observatory of Lyons during the third quarter of 1909. Observations were possible on sixty-seven days, the results being summarised in three tables, showing the number of spots, their distribution in latitude, and the distribution of the faculae in latitude.—**Ch. Gallissot**: The phenomenon of Purkinje. An experimental study of the luminosity of two points, red and blue. The brightness of these artificial stars could be altered by known amounts. It is concluded that Purkinje's phenomenon has no sensible influence from the sixth magnitude upwards.—**Arnaud Denjoy**: The measurement of ensembles.—**M. de Séguier**: The symmetrical group and the alternating group.—**W. Stekloff**: The development of an arbitrary function in series proceeding in accordance with certain fundamental functions.—**Joseph Marty**: Developments according to certain singular solutions.—**Sigismond Janiszewski**: Contribution to the geometry of general plane curves.—**M. Hadamard**: Liquid waves.—**Marcel Brillouin**: Questions of mathematical physics.—**A. Dufour**: Unsymmetrical triplets; an example of an asymmetry of position proportional to the square of the magnetic field. The chromium line 5247.56 forms a triplet in the magnetic field the axis of symmetry of which is displaced towards the violet. This asymmetry of position with respect to the initial line increases as the square of the field.—**E. Caudrelier**: The discharge of inductors: the capacity of the electrodes.—**André Kling**: A new method of estimating dextro-tartaric acid: The estimation is based on precipitation as calcium racemate.—**Léo Vignon**: The diffusive power of certain artificial colouring matters. A study of diffusion shows that dye-stuffs considered as soluble in water fall into two clearly differentiated groups; those of the first group, of which picric acid is the type, form true solutions; those of the second group are only apparently soluble, and are incapable of diffusion, such as Congo red.—**Pierre Dupuis**: The action of phosphorus trichloride upon guaiacol.—**Aug. Chevalier**: The forest resources of the Ivory Coast. Results of the scientific expedition in western Africa. The products include kola and coffee, both in the wild state, a gum analogous to gum arabic, and several gumm-resins.—**Auguste Joxe**: The modes of opening of achenes and kernels at the time of germination.—**Ed. Griffon**: Variation in grafting and asexual hybridation.—**Gabriel Vallet**: The penetration and bactericidal action of the ultra-violet rays with respect to the chemical constitution of the media.—**H. Bordier** and **R. Horand**: The action of the ultra-violet rays on trypanosomes. *Trypanosoma lewisi* in the blood of a rat was killed by an exposure for fifteen seconds to the ultra-violet rays of a quartz mercury vapour lamp. These trypanosomes were absolutely unaffected by a prolonged exposure to the X-rays.—**Mme. Marie Phisalix**: The natural immunity of batrachians and snakes against the poisonous mucus of the former: the mechanism of this immunity.—**A. Briot**: Properties of the serum of sero-anaphylactised rabbits.—**R. Robinson**: The dimensions of the caecum and typhlectasis.—**J. Thoulet**: A lithological submarine map of the coast of Languedoc.—**B. Galitzine**: The determination of the epicentre of an earthquake from the data of a single seismic station.

MUSIC.

Music: its Laws and Evolution. By Prof. Jules Combarieu. International Scientific Series. Pp. viii+334. (London: Kegan Paul, Trench, Trübner and Co., Ltd., 1910.) Price 5s.

THIS important work could only have been written by a musician who was acquainted with the history of music, and also had a considerable knowledge of sciences connected with music, such as mathematics, physics in relation to acoustics, physiology, psychology, and æsthetics. Almost every page shows the versatility of Prof. Combarieu in dealing with the various aspects of the subject, while his power of lucid description is conspicuous. There is also the graceful beauty of style peculiar to a Frenchman, and it has lost little or nothing in translation. The fundamental thesis of the book is that music is the art of thinking in sounds. According to the author, we can never hope to have an adequate conception of music unless we realise that it is a kind of intellectual activity associated with emotional states, but without those concepts that are the material of ordinary intellectual action. The study of acoustics, the study of sensations of tone, as was so fully carried out by Helmholtz in his first work, "*Tonempfindungen*," the study even of scales and major modes, are only to be regarded as contributions to a fuller understanding of music, although not a few writers, in dealing with these aspects of the subject, have deluded themselves with the notion that in so doing they were explaining the true nature of music. All this may be readily granted; but in justice to the physiologist and psychologist, on whom Prof. Combarieu now and then comes down heavily, almost with scorn ill-concealed, it must be contended that the foundation of music does consist of sensations, varying in kind and quality. The composer thinks in sounds which are related to each other according to laws well known to the composer, and which he often transgresses, and the master musical mind has a kind of instinct that perceives more deeply the hidden meanings of the phenomena of the cosmos and the still more ill-defined region of human thought and feeling.

Prof. Combarieu develops these ideas in a remarkable order. Instead of beginning with what is comparatively simple, the nature of vibrations, the mathematical basis of scales, &c., and the functions of the ear and brain in relation to sensations of tone, and then working onwards to the compositions of such men as Bach, Handel, and Wagner, he proceeds in the reverse order. First, he analyses a melody, showing how much there is in it that cannot be expressed in words, such as sensations of mere pleasure, the expression of emotional states, and the arousing of sentiments, and even trains of thought and of reminiscence, in the mind, and he arrives at the

conclusion that music is, as it were, the dynamics of emotional life. He traces the evolution of music, the simple melody, the canon originating in religious feeling, the discovery of counterpoint, the use of rhythm as connected with bodily muscular movements, and the early relation of music to magic. Next he examines the development of music as an expression of the gradually increasing complexity of social life, in this way accounting for the origin of octaves, fifths, thirds, and other intervals, and the development of the major and minor modes. Muscular work requiring cooperation among many individuals taught men rhythm and musical time, and, by slow degrees, the various modes of the Greeks, Lydians, Phrygians, &c., reflected the social life and habits of the Greeks. A confluence of these minor modes has resulted in the minor mode of the present day. In modern music there is a fresher and greater use of the minor mode and of chromatic intervals, and there is less satisfaction merely with consonance, a development quite in keeping with the anarchical state of thought and feeling characteristic of the present day. The development of the orchestra from primitive instruments is one of the most remarkable phenomena in the evolution of music, and modern composers now strive to write something appropriate for each instrument.

Prof. Combarieu makes some excellent observations on Darwin's well-known opinions on the sexual relations of music. It is in most instances the language of love, but a sexual theory will not account for all music. The chapter on the physiology of music is the least satisfactory in this valuable book. We do not think the author does justice to the work of Helmholtz, probably because he fails to grasp the theory of the cochlea and its difficulties. We cannot follow him in his notion that, in some way or other, the cochlea can, in a reflex way, adapt itself to different combinations of tones. Here he merges into metaphysical discussions that are beside the question. The last chapter or section on music and living beings is rather fanciful in describing analogies between well-known physiological phenomena and music. The illustrations he gives are analogies and nothing more.

Prof. Combarieu's book is very suggestive. He takes a noble view of music, an art which does not seem even yet to have reached its climax. Great as are the works of Bach, Handel, Verdi, and Wagner, each reflecting in a subtle way their individual genius, moulded by the circumstances in which they lived and the influences that conspired to make them great musicians, there may yet be in store for the human race even greater works, which, in their turn, will reflect the more complex conditions of civilisation, in even higher planes of non-conceptual thought, and in deeper knowledge and feeling. One may also suppose that in this further evolution the organs of music, the ear and the brain, will become more complicated. The evolutionary process has not ended.

JOHN G. M'KENDRICK,

E

HYGIENE OF THE NERVOUS SYSTEM.

Why Worry? By Dr. G. L. Walton. Pp. 275. (London: W. Heinemann, 1909.) Price 2s. 6d. net.

Self-Help for Nervous Women: Familiar Talks of Economy in Nervous Expenditure. By Dr. J. K. Mitchell. Pp. 202. (London: W. Heinemann, 1909.) Price 2s. 6d. net.

MUCH that a few generations ago it was usual to attribute to disorder of conduct is, by many, now placed in the category of functional nervous disturbance, and concomitantly it has been sought to relieve judicial and ecclesiastical officers of their duties and to devolve them upon the medical profession. In the two small books under review we find, expressed in popular language, that which amounts to a series of short sermons written by medical men, and for the most part addressed to those who are suffering from the effects of a lack of self-control. For one of our authors it is "not his aim to transform the busy man into a philosopher of the indolent and contemplative type," but to enable him to do his work effectively by eliminating undue solicitude. The other defends himself from the possible criticism that his advice is not new. We cannot suppose any such defence will be necessary. The advice proffered is that of Epictetus, Marcus Aurelius, and Seneca, but stops short, we may presume out of respect for the attitude of current science towards current religion, at the plane of these philosophers.

Dr. Mitchell points out how some of the conspicuous and peculiar virtues of women may become sources of trouble. Strong affections and sympathy are apt to lead to emotional excess, and such excess, whether spent in grief, love, hate, or ambition, is the most extravagant form of nervous expenditure, and may eventuate in bankruptcy. A very frequently predisposing cause of nervousness is the too ready yielding to emotional expression, along with the cultivation of an excessive manifestation of emotion in speech and manner. Many women account it an attraction to give way to tears for trifling pains, or to loud complaints expressed in exaggerated language about small annoyances, and it is pointed out to these that to endure the smaller inevitable woes with equanimity is to form a habit which shall be of immense service when the larger troubles arise.

Much useful advice is given upon those physical causes which tend to develop nervous manifestations, or to exaggerate them when they are already present. On one hand there is a large number of persons who attribute many trifling derangements of various organs to their "nerves," and, on the other hand, there are others who fail to recognise their disorders as being nervous in origin until severe mental symptoms arise, and each class will find the information which may be gathered from these books of great help. Due attention, neither too prolonged nor too scanty, to the hygiene of the nervous system will in the future doubtless go as far as prophylactic hygiene has already gone in connection with the other systems, and it must be recognised that the education of the child is in this connection of paramount importance. Something between Spartan severity and

the opposite extreme, to which there seems to be a serious danger of our passing, is the educational goal to which we should press, to the development of that degree of self-control which shall avert the nervous weakness which issues in each petty emotion usurping entire control over the body.

For those who are "nervously" disposed we can ask for no better advice than that given in the small volumes before us, and we should certainly feel assured that those who would read the books and would endeavour to act upon the suggestions therein contained were well on the road to recovery. Unfortunately, there is an enormous residue of patients who will listen to no advice, though they pay a man to give it them, and yet another class which, while recognising the advice given to be sound, seems wholly incapable of the amount of self-help requisite to acting upon it.

MYCOLOGICAL WORKS.

- (1) *Researches on Fungi.* By Prof. A. H. Reginald Buller. Pp. xi+287. (London: Longmans, Green and Co., 1909.) Price 12s. 6d. net.
- (2) *Die Würzelpilze der Orchideen, ihre Kultur und ihr Leben in der Pflanze.* By Dr. Hans Burgeff. Pp. iv+220; 3 plates, and 38 figs. in text. (Jena: Gustav Fischer, 1909.) Price 6.50 marks.
- (3) *Fungi and How to Know Them: an Introduction to Field Mycology.* By E. W. Swanton. Pp. xi+210. (London: Methuen and Co., 1909.) Price 6s. net.

(1) DR. BULLER'S investigations, undertaken with the object of throwing light upon the production, liberation, and dispersion of spores in the group of fungi known as the Hymenomycetes, breaks new ground, and, as usual in such instances, will undoubtedly form the starting point of future research on the part of many students. A brief sketch of the components of a typical hymenium or spore-bearing surface are first dealt with. It is pointed out that swollen gill-margins serve to separate the gills, otherwise the spores could not be shed. This may be true in those instances where thickened gill edges exist, but in at least seventy-five per cent. of known agarics the edge of the gills is not in the least thickened.

Under nuclear phenomena it is pointed out that the passage of the nucleus from the basidium through the very narrow sterigma into the spore affords striking evidence of protoplasmic plasticity. This point has been previously emphasised by Wager. The classification of the Agaricineæ according to spore colour is dubbed as a purely artificial arrangement, but no valid reason for this statement is forthcoming. The author does not appear to realise that what the systematist understands by black spores are spores thrown down in the mass; no spores are black, even under the microscope, but they may be opaque, and consequently appear to be black.

In a work devoted to research it is generally assumed that the author is conversant with what has been done previously on the same subject; this, however, does not hold good in the present instance; for

example, the occasional sterility of the gills, which consequently remain colourless in species normally producing coloured spores, has already been discussed in more than one text-book, and the conclusion arrived at is identical with that advanced by Dr. Buller. Cystidia are included in the category of hair formations. Probably the definitions as to the origin of hairs are various, but certainly true cystidia—not to be confounded with swollen marginal cells—originate from deep-seated cells.

Coming to the crucial point of research, the liberation of spores, it is at once obvious that the author attempts generalisations on too narrow a basis, as proved by the following quotation:—

"Excepting a few gelatinous species which require further investigation, it is a general rule that in Hymenomycetes the hymenium is situated on the under side of the fruit bodies."

He has ignored, or does not realise, the existence of many hundreds of species included in the Hymenomycetes where the hymenium is on the upper surface of the sporophore, and pointing upwards, as in Corticium, many species of Stereum, Hymenochaete, Peria, &c., yet such species are as numerous and cosmopolitan in distribution as the species with which he is acquainted.

In the Agaricineæ and the Polyporeæ it is considered that the position of the hymenium on the under-surface of the sporophore has been primarily decided as affording the greatest facility for spore dispersion. The spores are very adhesive when fresh, hence to secure successful liberation the gills or tubes must occupy a vertical position, which is secured by the rigidity of the sporophore. Gravity is the principal orienting stimulus acting on the sporophore. The spores on a basidium are discharged successively; each spore is shot out violently to a distance of about $\frac{1}{10}$ mm., and afterwards falls vertically downwards. The horizontal projection of the spores necessitates that gills should be placed at a certain distance apart. The process of spore liberation is treated in detail. Some very ingenious and interesting observations on the rate of fall of spores are furnished, which, subject to modification owing to their size, specific gravity, and process of desiccation, ranges from 0.3 to 6.0 mm. per second. The specific gravity of spores is determined approximately by using heavy fluids contained in a counting apparatus. In the genus Coprinus the gills are usually stated to deliquesce, or melt into a black, inky fluid, and it was generally assumed that the spores were contained in this fluid. According to Buller, however, the spores are shot off and fall as in other Agarics, commencing at the margins, and when a narrow zone of the gill is depleted of spores, the naked portion of the gill is consumed by a process of autodigestion. A most interesting account of the means by which the spores falling from a fruit-body may be seen by the use of a concentrated beam of light is given, but perhaps the most unexpected phenomenon explained is the fact that the sporophores of certain fungi retain their vitality for years in a dried condition, and, after the application of wet cotton-

wool, quickly revive and begin to shed their spores, a process which continues for some days.

It is estimated that the giant puff-ball produces 7,000,000,000,000 spores, also that only one spore out of about 20,000,000,000 spores ever succeeds in producing a mushroom capable of reproduction. In addition to the many valuable new discoveries and new theories bearing on subjects previously investigated by other observers, the book abounds with suggestions and sidelights which cannot but prove of immense service to future workers.

Ten plates and numerous excellent figures in the text are of much value in following and grasping clearly the various points raised by the author.

(2) Notwithstanding the extensive researches of Frank, Bernard, and others bearing on the relationship between fungi and the roots of phanerogams, resulting in the structures known respectively as ectotropic and endotropic mycorrhiza, much yet remains to be done before we are in a position to formulate the significance of such combinations. Dr. Burgeff has contributed considerably to our knowledge in this respect, and has added many new facts bearing on the nature and life-history of those fungi met with in the roots of orchids. Fifteen different kinds of fungi were isolated and carefully studied from pure cultures. The majority of these produced asexual reproductive bodies, mainly under the form of long chains of minute conidia of the oidium type. No higher form of fruit was observed, hence the systematic position of these root-fungi yet remains to be determined.

Wahrlich's view that certain of the fungi found in the roots of orchids belonged to the genus Nectria has not been corroborated by Burgeff. Sclerotia are sometimes produced. On account of the general resemblance of orchid fungi to those of Rhizoctonia, Bernard placed all the forms he isolated from orchids under the last-named genus. Burgeff, on the other hand, has created a new genus—Orcheomycetes—for the reception of his various forms, which are named specifically after the host from which they were isolated; thus the form isolated from *Ophrys apifera* becomes *Orcheomycetes apiferae*. The wisdom of creating new generic and specific names for admitted form-species is doubtful, more especially as the author states that such names have no systematic importance or significance. The group characters are based on the behaviour and mode of growth of the fungus, as a pure culture, on the substratum. The specific features turn on the nature of the hyphæ, form and size of conidia, some of which are comparatively large, and in some instances there are indications of the formation of pycnidia.

All the described forms are of endotropic origin, truly ectotropic mycorrhiza occurring only very seldom in orchids.

The question of nutrition in cultures was investigated, and the important fact noted that no assimilation of free nitrogen took place. All the species are aerobic.

The concluding part of the work deals with the

infection of the seed, and the future development of the fungus until the host reaches maturity.

Numerous excellent figures illustrate the different kinds of fungi isolated, also the progress of the fungus from its first entrance into the seed.

(3) An introduction to field mycology was a desideratum, and, unfortunately, still remains to be written. The present work is practically an imperfect mycological *vade mecum*, attempting to deal with every phase of the subject, instead of being confined to an introduction to field mycology, as stated in the subtitle. The first chapter deals with the general structure and morphology, and has obviously been culled from preceding works of very different dates, as some of the information is up to date, some of historical interest only, and some inaccurate, as the statement that in the Ascomycetes the paraphyses are probably abortive asci. Immediately following this statement it is announced that the paraphyses are a continuation of the vegetative hyphæ, which is a fact, and consequently precludes the possibility of their being abortive asci. Interesting chapters on the dispersal of spores, parasitism, habitats, &c., follow. The remarks on edible and poisonous species consist of platitudes, and leave the student in doubt. The Jew's ear is not an esteemed esculent in some countries, but *Hirneola polytrichi*, an allied species, is.

Coming to the essential portion of the book, it is at once apparent that the author is one of those who consider that the name of a fungus is a point of primary importance; in fact, there is but little indication that anything else is of any importance. In dealing with the systematic side of a subject, it is universally conceded that the student should be first introduced to the primary groups, and approach by degrees to entities or species. The reverse order, however, is followed in the work under consideration. Families and genera are simply dealt with briefly by a key system, which the beginner cannot possibly grasp, whereas the species are described in detail, the result being that if the species are recognised at all, it will be by a rule-of-thumb method, and his knowledge of affinities will remain at zero. Experience has shown that when a student commences the study of mycology by dealing first with individual species, his knowledge rarely extends beyond recognising a given fungus by name. It is doubtless the same in other branches of science.

The specific descriptions are very uneven, some being technical and beyond the grasp of the beginner; others are altogether inadequate, whereas in the Ascomycetes no mention is made of the asci or spores, the only features of real importance. The statement that *Bulgaria polymorpha*, an ascigerous fungus, is the conidial form of *Ulocolla foliacea* might be regarded as a slip if many other equally glaring mistakes did not suggest lack of knowledge of the subject undertaken. The illustrations are numerous, consisting of sixteen coloured and thirty-two black-and-white plates. Many of the figures are good, some are poor, and some are mere parodies of the object they are intended to represent.

NO. 2108, VOL. 83]

ELEMENTARY CHEMISTRY.

(1) *Elementary Chemistry*. By Hollis Godfrey. Pp. xiv+456. (New York and London: Longmans, Green and Co., 1909.) Price 4s. 6d. net.

(2) *Systematic Qualitative Analysis*. By Dr. R. M. Caven. Pp. xii+240. (London: Blackie and Son, Ltd., 1909.) Price 3s. 6d. net.

(1) **W**E have carefully read a considerable part of Mr. Hollis Godfrey's book, and have reluctantly come to the conclusion that as an elementary text-book it is not a complete success. It is true that the book contains much useful information, which is well arranged, that it is well printed and luxuriously illustrated, and that its general appearance is attractive; but the explanations are slovenly, the similes are childish, the historical references betray a curious ignorance of the original memoirs, and many of the illustrations, excellent though they are as photographs, are peculiarly inept.

We have, for example, a picture of an apple to represent "acids in nature," two views of a rather nondescript landscape to illustrate "earth compounds," a female haymaker looking at her watch with a haystack in the background to explain atmospheric pressure, another party of haymakers looking at a tiny spot in one corner of the picture (a balloon presumably) to indicate the lightness of hydrogen, and so on.

A few extracts will illustrate the other points above mentioned. "Chemistry is a science which explains the every-day things of life" (p. 2). "There are seventy or eighty different atoms" (p. 9), meaning of course, different kinds of atoms. As a kind of corollary to this the author states that "since masses are made by the union of molecules, there exist only between seventy and eighty perfectly simple substances, &c.," forgetting a previous paragraph in which he defines a hypothesis as a belief, and the more important fact that the elements would continue to exist independently of any atomic hypothesis.

The same kind of loose treatment is extended to volume and weight.

"If we have the same volume, the same size piece, so to speak, we can tell at once whether one substance is heavier or lighter than another. But unless we have the same volumes we can tell very little about it" (p. 23).

Again, on p. 40, it is stated,

"A hot-air balloon rises because the air within the balloon bag heated by the flame, expands, grows less in weight and so pulls the light envelope up."

We have still to learn that dough rises owing to the growth of the yeast cells (p. 281). The relation of oxygen to ozone is compared to a man who disguises himself and assumes another name when engaged in crime. The catalytic action of manganese dioxide on potassium chlorate is compared to a person working in the dark and then in daylight.

"The sun comes out and floods the room with cheerful radiance. The man's hands work faster—swifter and swifter grow his motions, &c."

The references to the history of chemistry may be illustrated by the following extracts. We are told (p. 28),

"The explanation of the loss or gain in weight on burning *tasked* the best efforts of the whole scientific world for a couple of hundred years,"

and this is followed by an account of Priestley's discovery of oxygen which even his greatest admirers would scarcely sanction. After stating that Priestley burned quicksilver in the air and obtained a red powder, he goes on:—

"The experiment so far was no different from what had been done before, without result, but Priestley, with that brilliant imagination which has so often characterised the great leaders of science, saw a new possibility. If mercury had changed to a red ash by burning, could not the substance which had so changed it be obtained from the red ash in its original form by heating?"

Cavendish's discovery, we are told further on, settled questions which had troubled men of science for two centuries. To the question, "What is water?" Cavendish gave the reply, "It is hydrogen oxide."

Sufficient has been said to illustrate the peculiar defects of the book, and it is not a little surprising that none among the ten ladies and gentlemen named in the preface to whom the MS. and proof were in turn submitted should have directed the author's attention to them.

(2) Although we are deluged with books on qualitative analysis, Dr. Caven's new volume may be regarded as by no means a superfluous addition to the number. He starts on the perfectly correct assumption that qualitative analysis, properly studied, may serve as a foundation for a sound knowledge of practical and theoretical inorganic chemistry, and develops his method along these lines. There is, of course, a great deal about group reagents and tables of separation which are common to most books on the subject, but there is, in addition, a useful general introduction, which is clear and concise, and a final chapter on the systematic examination of inorganic substances. The author does not tell us for what class of student the course is intended, and now that it is becoming the fashion to serve up chemistry to suit the diverse needs of different classes of students, or, as someone expressed it, to sell it in assorted penny packets, we doubt whether any but the embryo professional chemist could give the time necessary to complete it.

It is doubtful, too, if it is desirable for any student to postpone quantitative work until so much qualitative analysis has been assimilated.

Experience shows that an early acquaintance with the former is an excellent discipline in careful manipulation and exact observation, and the best antidote to untidy and sloppy habits of work. J. B. C.

OUR BOOK SHELF.

La Vita di Michele Faraday. Narrata da Andrea Naccari. Pp. 370. (Padova: Fratelli Drucker, 1908.) Price 3 lire.

THOUGH there exist four well-known biographies of Faraday in the English language, one only, the brief essay by Tyndall, "Faraday as a Discoverer," has been translated into Italian. Neither, until the appearance of the work now under review, had any Italian biography of Faraday been written. Prof. Naccari,

whose position as professor of physics in the University of Turin guarantees his competence in physical science, and who is himself an experimental investigator of some distinction, has now written a life of Faraday which worthily presents the career of our great countryman. He has drawn freely and with due acknowledgment from all the four English biographies, and has had the advantage also of being in possession of the volume of printed correspondence between Faraday and Schönbein, which was published more recently than any of the four. Thus, without being either encumbered with the mass of details of Bence Jones's authoritative memoir, or restrained within the smaller compass of the three smaller biographies, he has been able to produce a work which in certain aspects is the most satisfactory life of Faraday yet compiled. He has not failed to incorporate the newer material while preserving what was of permanent value in the old.

The life-story follows the familiar lines. The author has not been able to add anything to our knowledge of the doings or wanderings of Faraday in Italy as the assistant of Davy in his eighteen months' tour of 1813-15. Neither has he thrown any further light upon the episode of the misunderstanding between Faraday and Nobili and Antinori in 1832 respecting their supposed correction of errors which he had not committed. In the author's preface he states that in his first ten chapters he has considered the man rather than the philosopher, with the intention to make him known and to make him loved. In his eleventh and last chapter, which occupies more than one-third of the book, he treats of Faraday's scientific work. Here he follows conscientiously and skillfully the evolution of Faraday's discoveries in their chronological order, but discusses them in their relation to modern views and discoveries. He lays great stress upon Faraday's electro-optic pioneering discoveries as having been provocative of so much of the later developments of physics. He concludes by citing a characteristic passage from the peroration of one of Faraday's last Royal Institution discourses in 1858.

The book is not illustrated by any cuts. It avoids all mathematical expressions; but it is eminently readable, and is well printed. English men of science owe a debt of gratitude to Prof. Naccari for his faithful presentation of one whose memory they so highly honour.

Botanisch-Mikroskopischer Praktikum für Anfänger. By Prof. Martin Mobius. Zweite Auflage. Pp. xi+123. (Berlin: Gebrüder Bornträger, 1909.) Price 3.20 marks.

THE exercises, sixty-four in number, contained in this little book are designed to make the student familiar with the outlines of plant structure in the chief subdivisions of the vegetable kingdom. The directions for making and mounting the preparations are clear and good, and the text is not overburdened with the details which the student ought to learn from the preparations themselves. The illustrations, which are diagrammatic, may also be found useful, although we think the work would not have been impaired in value had they been omitted. The fact that a second edition has been reached proves that its author has met a need felt for such a book, but it seems odd to discover the statement that the aleurone-containing cells of the castor-oil bean belong to the cotyledons (Keimblätter). We also prefer the style of *Ranunculus acris* instead of *R. acer* (p. 9, &c.). But on the whole the book is useful, well printed, and sensibly bound, and its price is moderate.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. No notice is taken of anonymous communications.]

Fertilising Effect of Soil Sterilisation.

WITH further reference to the work of Messrs. Russell and Hutchinson on soil sterilisation (*Journal of Agricultural Science*, October, 1909), it may be interesting to record some information of which I have recently become possessed.

Some of the large growers of cucumbers, tomatoes, &c., under glass for the London market have for some little time adopted the plan of injecting jets of steam into their soil before planting, not with any view of increasing its fertility, but with the view of destroying slugs, insects, &c. In the experience of some growers the productivity of the soil after steaming has become so greatly increased that, if anything like the usual quantity of stable manure is mixed with the soil, the plants grow with such rank luxuriance as to spoil their bearing capacity, exhibiting all the symptoms that would be expected as the result of a heavy overdose of nitrogen.

This experience has been communicated to me by growers who were previously unaware of the Rothamsted work. At the moment they were feeling in somewhat of a dilemma: if they did not steam the soil they suffered from insect pests; if they did steam it they were obliged to curtail the supply of stable manure, at the expense of lowering the subsequent soil temperature, which is normally maintained at a high level by the fermentation of the manure. No doubt means may be found of adjusting the various conditions satisfactorily, but meantime the observation appears to afford striking independent confirmation on a practical scale of the indirect fertilising effect of partial sterilisation in killing off the phagocytes or protozoa which normally keep down the numbers of those bacteria the task of which is to turn organic nitrogen into plant food.

BERNARD DYER.

17 Great Tower Street, London, E.C., March 15.

Certain Reactions of Albino Hair.

IN a note in the *Journal of Physiology* (vol. xxxviii.) on the chemical nature of albinism, Mr. Mudge describes some interesting observations which he made upon rats' skins. Starting with the presumption, based upon the work of Miss Durham and Cuénot, that an albino carries a chromogen and lacks the ferment necessary to produce pigment from it, and supposing that fermentation is a process of oxidation or reduction, Mr. Mudge argued that it might be possible to produce pigment artificially by means of an oxidising or reducing agent. He found by experiment that immersion of albino rat skins in a solution of 10 per cent. formalin and 70 per cent. alcohol in equal volumes resulted in a "vivid yellow colour" in the hairs; he further states that these coats, when washed in water and immersed in H_2O_2 (20 vols.), become changed in colour from vivid yellow to a "brownish tint" in about twenty-four hours. He adduces arguments to show that the coloration is due to the presence of a specific body in the hairs diffused through the keratin, and not to mere reaction between the keratin and the formalin.

I have repeated these experiments with various skins. In the case of the single albino rat skin which I used, the vivid yellow was obtained immediately on immersion in the formalin mixture. The change to brown in H_2O_2 was not obtained, but complete decoloration resulted from immersion in this reagent. Prolonged immersion in the formalin mixture also produced almost complete decoloration.

With guinea-pig albinos carrying, respectively, black, chocolate, and red, negative results were obtained, as they were also with a single mouse skin.

What struck me as particularly interesting in connection with the yellow colour produced by the formalin mixture in the coat of the albino rat is the fact that it is a peculiar canary-yellow, which I remember to have seen elsewhere among mammals only in members of the stoat family when the winter whitening is incomplete. A piece of pale yellow stoat fur acquired a much more intense yellow colour as

a result of twenty-four hours' immersion in the formalin mixture; a similar piece was decolorised by H_2O_2 . There can thus be little doubt that the yellow body produced artificially in the fur of the albino rat is a substance similar to the yellow pigment of the stoat's winter coat, and therefore probably represents a stage in the reduction of the pigment to the condition in which it exists in the white hairs.

Miss Durham tells me that it is a well-known fact that albino rats do not remain pure white if they are exposed to the action of light. Just as darkness is necessary for the production of a pure white coat in the rat, so a certain degree of cold seems necessary in the case of the stoat tribe, though in their case a change to a warmer climate does not at first prevent the usual colour-change in winter. Thus Eric Parker, in "The Book of the Zoo," points out, concerning a certain foreign pine-marten, that "the first winter he spent in the Garden his fur turned almost white to match the snows he would naturally have expected. The last two winters it remained brown, though it has lightened considerably towards yellow." This repetition of a periodic act without the usual stimulus recalls certain phenomena in plants, which Mr. F. Darwin attributes to memory.

IGERNA B. J. SOLLAS.

Nitrogen-fixing Bacteria and Non-leguminous Plants.

MAY I be allowed to direct attention to two errors in Mr. Hall's letter in NATURE of December 23, 1909?

Mr. Hall states that "Pseudomonas and Azotobacter together (1.24) are less effective than when grown separately (0.91+0.56)." This comparison is incorrect. The fixation of free nitrogen by bacteria is estimated in terms of milligrams of nitrogen per unit of carbohydrate in the culture solution. Pseudomonas and Azotobacter together give 1.24 N for one unit of carbohydrate. Pseudomonas and Azotobacter grown separately give 1.47 N for two units of carbohydrate, hence the correct comparison is:—

Pseudomonas and Azotobacter together	Per unit = 1.240 N
Pseudomonas and Azotobacter separately = $\frac{1.47}{2}$	= 0.735 N.

Hence my conclusion that Pseudomonas and Azotobacter together are more effective than when grown separately is, I think, justified.

The second error has reference to a mean experimental error of ± 10 per cent. Mr. Hall writes:—"By an error which the context rendered sufficiently obvious, I wrote 'oats' instead of barley when dealing with Prof. Bottomley's first-quoted experiment with soil." May I point out that oats were the only plants mentioned in the "first-quoted experiment with soil"? Even if the increase of barley (13.6 per cent.) be taken, one fails to see how it is "sufficiently obvious" that a mean error of ± 10 per cent. more than covers an increase (the lowest of the results quoted) of 13.6 per cent.

W. B. BOTTOMLEY.

King's College, Strand, W.C., February 16.

A Sample of Spurious Correlation.

THOUGH regretfully unable to do justice to the mathematical reasoning of Dr. G. T. Walker in NATURE of January 6, I may, perhaps, be allowed to say that it is of the essence of the method that those dots (each expressing a comparison of two sums of thirty items) tend to arrangement in a straight band, or strip, with fairly defined borders. It is expected that future dots will generally come within those limits; but to affirm this in a given case, to say, e.g., that the next dot will not be below a certain level, is it not, necessarily, to say something quite definite as to the character of the coming season, as that its rainfall, frost days, or other feature considered, will not be below a certain numerical value? If the one statement is warranted, so (by the nature of the case) is the other. Thus the essential point seems to me to be whether the past distribution of those dots affords a reasonable clue to their future distribution, and I do not see that my critic throws doubt on this.

I think (with all deference) that anyone who will give the method a full trial will find it distinctly helpful in a number of cases (I do not say in all).

ALEX. B. MACDOWALL.

8 Marine Crescent, Folkestone, January 14.

IN my former letter in *NATURE* of January 6 I attempted to prove that the arrangements of dots in a band would occur even if the numbers of which the sums were taken were entirely independent of one another, in which case a forecast regarding one of the numbers could not possibly be made from knowledge of the remainder. A forecast could only be made if it were shown that the width of the band were smaller than would be expected on the hypothesis of pure chance, and this vital point has received no consideration.

The situation may be made clearer by reference to the original letter in *NATURE* of September 16, 1909. The essence of the method is that, if we were forecasting for 1910, the dot the two rectangular coordinates of which are the sums of data for thirty years up to 1909 and 1910, respectively, will lie near to a line through the origin at an angle of 45° with the axes. Thus the sum of the data from 1880 to 1909 will be nearly equal to the sum of the data from 1881 to 1910, or the data for 1880 and 1910 will be nearly equal. If the nearness to equality has any value at all for forecasting, this is equivalent to asserting that the data in question tend to be repeated after thirty years, or have a thirty years' period; but as the same result could be reached if 25 or 35, or any other comparable number, had been substituted for 30, it will be seen that the reasoning cannot be free from error.

That the nearness to equality is inadequate is clear from the diagram in the original letter. The edges of the band there intercept a length representing about thirty-six days along any vertical ordinate. Hence all that can be inferred in forecasting for 1910 is that the number of hot days will probably not differ by more than ± 18 from the number of hot days in 1880; and as the average number of hot days in a year is stated as fifteen, it appears that a forecast so entirely vague could be made without any analysis whatever.

GILBERT T. WALKER.

Kodaikanal, February 21.

SOME SCIENTIFIC CENTRES.

NO. XV.—THE MOUNT WILSON SOLAR OBSERVATORY OF THE CARNEGIE INSTITUTION OF WASHINGTON.

MOUNT WILSON rises 6000 feet, almost abruptly, from the plain in which lie the twin cities of Los Angeles and Pasadena. From the mountain top these cities appear at night as glittering star-clusters; by day they are seen through a haze of dust which the ascent of the mountain has put below our feet. Beyond is the vast Pacific; above our heads the glorious sky of California; around us the buildings of perhaps the best equipped observatory in the world.

These words are written by anticipation. Prof. Hale has invited the International Union for Solar Research to hold its next meeting on Mount Wilson on August 29, 1910, and astronomers and physicists from all parts of the world are eagerly looking forward to the occasion. The present writer is not, however, altogether a stranger to the scene; he was on Mount Wilson in 1904; but at that time the observatory was in its infancy. It had not even been decided on what scale it was to be designed. Prof. Hale had realised the magnificent opportunities offered by the climate and site, and he had made urgent application to the Carnegie Institution for funds adequate to deal with the serious difficulties to be overcome; but he had also resolved that, if his application was not granted, there should still be a solar observatory on Mount Wilson, for which he would himself provide the funds, so that he had already commenced building operations. Nevertheless, the utmost provision which he and his courageous wife could afford to make would naturally fall far short of what was needed for a suitable observatory, and he was therefore anxiously awaiting the answer of the Carnegie Trustees. Fortunately for astronomy, it was favourable; and since it was received one marvel has followed another in rapid succession. The visitors will be drawn to Mount Wilson as to the

main focus of astronomical enterprise and success at the present moment.

The first of the principal instruments to be completed was the great horizontal *Snow* telescope, originally constructed at the Yerkes Observatory, with the aid of funds given by Miss Snow, of Chicago. The concave mirror, of 24 inches aperture and 60 feet focus, is fed by a coelostat with plane mirrors of 30 inches and 24 inches, the beam of light being sheltered by a house specially designed to guard against temperature effects. To this telescope can be attached a spectrograph of 18-feet focus, or a 5-foot spectro-heliograph. The heavy parts of the apparatus are mounted on massive stone piers, built with great labour, since it was found that the stone in the neighbourhood was unsuitable, and that materials had to be brought up from a lower altitude by mules.

But, successful as this powerful instrument has been, it has also served to point the way to possible improvements. Experience of its working suggested that a *vertical* telescope might be in various ways better than a horizontal one; and accordingly a "tower" telescope was constructed, with the coelostat mounted on a tower 60 feet high, built as a skeleton framework. This experiment was so successful that a more ambitious one was at once projected, and a tower 150 feet high is under construction. As wind pressure will be much more serious on this new structure, Prof. Hale has adopted the ingenious device of building an outer tower for protection, surrounding every bar of the inner tower by a tube of the outer. The lower parts of these tower telescopes are contained in wells sunk many feet into the ground.

Thirdly, there is the beautiful 5-foot reflector, made by Prof. G. W. Ritchey, who has already proved his skill in such work. The mirror was made at the Yerkes Observatory some years ago, but has had to wait until a mounting could be provided on Mount Wilson; and, indeed, there was a still earlier provision to be made; the track up the greater part of Mount Wilson was originally only 3 feet wide—a mere ledge in a precipitous descent—and up this narrow track the materials and instruments were carried, at first on mule back, later in a specially designed carriage, with steering fore and aft, and drawn by a mule. But the 5-foot mirror and its mounting could not be taken up in this way, and it was necessary to widen the track to 5 feet throughout its whole length. This was not accomplished without serious delays, owing to severe storms, which sometimes destroyed weeks of labour; but it was finally completed, the instrument was taken up and mounted, and at the meeting of the Royal Astronomical Society on December 10, 1909, were shown some photographs of Mars taken with this great telescope which far surpassed anything of the kind yet seen, and for which the president was requested to convey a special vote of thanks.

A still larger telescope, with a mirror 100 inches in diameter, is to be attempted on Mount Wilson, but is not yet within sight of completion. Round the existing three great instruments are grouped a number of other buildings; first and foremost a physical laboratory, so indispensable now in astrophysical work; also an astrophysical museum, and a variometer house; and then such necessary accompaniments as a power-house, a pump-house, storage-houses, and dwellings. The establishment is not adapted for ladies and children, and the chief residence is called the "Monastery." Distressing news reached us recently that the "Monastery" had been burnt down, owing to the carelessness of a temporary servant. Fortunately it contained no original photographs or records, and most of the books had been

taken down to Pasadena, but many were burnt. The building and contents were insured, but re-building cannot be commenced until after the close of the rainy season in the spring, so that the observers will be put to some inconvenience during the next few months, though there are now so many residences on the mountain that they can find temporary quarters.

In Pasadena, 6000 feet below, are the instrument shop, office, physical laboratory, &c. Here also dwell the wives and families of the observers. There is, of course, communication constantly by telephone and frequently by personal visit between the two departments of the observatory. Much practice has made the observers expert and rapid climbers.

Prof. G. E. Hale at the 30-foot spectrograph of the 60-foot tower telescope, arranged for photographing the spectrum of a sun-spot with rhomb and Nicol prism.

Our thoughts naturally turn from the contemplation of so magnificent an installation to the man who designed it, and has brought it to such perfection of efficiency in the short space of six years. It is, of course, not the first achievement of Prof. Hale. Just six years ago it fell to the lot of the present writer to review his work on the occasion of the award to him of the gold medal of the Royal Astronomical Society. That work already comprised the successful inception of the spectroheliograph and its use in depicting the "floculi" at various "levels" in the solar atmosphere (the connotations of the terms in inverted commas having been suggested by the medallist only a few weeks before); also a consider-

able piece of work on the spectra of fourth-type stars; also the foundation and equipment, not only of the private observatory at Kenwood (Chicago), but of the great Yerkes Observatory, with its giant telescope and other magnificent resources for the study of astrophysics; also the establishment of the *Astro-physical Journal* as an indispensable aid to workers. Such a record might well have contented an ambitious man at the end of a long life, but it is not too much to say that Hale has in the intervening six years eclipsed these achievements, together and separately, by new ones. The workers who had been put in communication by his *Journal* have been drawn into closer companionship by the International Union for

Solar Research, which he inaugurated at St. Louis in 1904, and which he has invited, after meetings at Oxford (1905) and Meudon (1907), to meet at Mount Wilson this year, as above stated. His record of work now includes the photographic mapping of the sun-spot spectrum (a long-standing problem solved) and the discovery of magnetic vortices in the sun—a truly sensational discovery, and one which is certain to lead to others; and his work in founding the Yerkes Observatory has been treated as preliminary to the real business of adapting the splendid Mount Wilson Observatory, point by point, to the pressing needs of solar physics.

We should lose a valuable lesson if we did not note the steady progression in enterprise which has built up the success. Prof. Hale has several times publicly insisted upon the value of work with modest apparatus, such as he began with himself. During a visit to England in 1907, he gave an address to the Royal Astronomical Society on "Some Opportunities for Astronomical Work with Inexpensive Apparatus" (Mon. Not. R.A.S., lxxviii., p. 64), which not only emphasised the value of such work, but gave a number of concrete suggestions to intending workers. The difficulties of making a beginning are well known; but those who earnestly consult this lecture will find most of them removed. It is, of course, assumed that there is a desire to work; Hale addressed himself to "the amateur," defining him as "the man who works in astronomy because he cannot help it, because he would rather do such

work than anything else in the world, and who therefore cares little for hampering traditions or for difficulties of any kind." These noble words are not only a stimulus; they also clearly reflect the character of the man who uttered them, and go far towards explaining his success. For the rest, we may accept his own estimate of the importance of beginning with small means, and of the value (several times emphasised in letters to the present writer) of the encouragement of his father. His father bought him a telescope (an excellent 4-inch Clark), but not until he had first made one himself; his father also bought him the spectroscope with which he first photographed a spectrum, to his huge delight, but this was not

until he had first worked with home-made apparatus; his father built the Kenwood Observatory, but not until his son had matured his plans by work at Harvard and elsewhere. "His policy always was," writes the son in one of his letters, "to induce me to construct my first apparatus, and then to give me a good instrument if my early experiments were successful." On the death of this wise and kind father, his children established, in pious and affectionate memory of him, the "William E. Hale Fund" for the encouragement of research, which has already aided, in an unobtrusive but none the less efficient manner, several scientific projects of different kinds. His lessons are so deeply impressed on the mind of his son that in the address above referred to he said, "with all seriousness, that it is a fair question whether large observatories, with powerful instrumental equipment, should be established, if they tend to keep back the man who is pursuing the subject with less expensive appliances, and is introducing, through his careful consideration of the possibilities of research, the new methods which in the process of time will take the place of the old ones."

A few facts and dates may be given here. George Ellery Hale was born in Chicago on June 29, 1868 (a few months before the classical observations of prominences without an eclipse, on which he was to build his main work), the son of William E. and Mary S. Hale; he married in 1890 Miss Evelina S. Conklin, of Brooklyn, N.Y., and has a daughter and a son. He entered the Massachusetts Institute of Technology (Boston) in 1886, taking the course in pure science, and graduating S.B. in 1890. He spent some time at the University of Berlin in 1893-4. While in Boston he was enabled, by the kindness of Prof. E. C. Pickering, to spend his spare time at the Harvard Observatory, doing any work assigned to him. The principle of the spectroheliograph occurred to him in the summer of 1899, but experiments were not then successful. He first photographed the prominences in the spring of 1891, within a week or two of similar successes by C. A. Young and Deslandres; but this achievement must be carefully distinguished¹ from the construction of the first successful spectroheliograph, in which Hale had a clear lead of all other workers. It was completed in January, 1892, and from that time regularly recorded, at the Kenwood Observatory, prominences and faculæ. Before the end of 1892 the project for the great Yerkes Observatory was already on foot, and was completed in the autumn of 1897. We may note in passing two incidents of that early history; first, that the project originated in a chance conversation with Alvan G. Clark at the Rochester meeting of the American Association for the Advancement of Science. Hale then learnt of the existence of two discs of glass available for a large telescope, and immediately began the search for a Mæcenas. Such incidental results of scientific gatherings are sometimes forgotten in estimating their value. Secondly, after several applications had failed, when ultimately the matter was laid before the late Mr. C. T. Yerkes, he replied at once, inviting President Harper and Mr. Hale to call upon him, and telegraphed for Mr. Clark as a result of the interview. His rapidity in decision seems to have been noteworthy, even in Chicago.

It would unduly extend this brief notice to follow the history of the Yerkes Observatory during the years from its completion in 1897 until Hale handed over the directorship in 1904 to Prof. E. B. Frost,

¹ It does not seem to the present writer that the late Miss A. M. Clerke has been sufficiently careful to distinguish these two distinct steps in her otherwise admirable writings (see, e.g., "Problems in Astrophysics," pp. 18 and 98).

in order to devote himself to the Mount Wilson Observatory. One is sometimes tempted to peer into the future; from Kenwood to Yerkes, from Yerkes to Mount Wilson, from Mount Wilson to —? Does a fourth term of the series ever occur to Prof. Hale in his dreams? Series are treacherous to deal with; "it is most unpleasant," once remarked an eminent mathematician who has devoted part of his life to them, "to dream that you are expanded in an infinite series, and that it will not converge." There is a notable divergence in the series of observatories with which Prof. Hale might identify himself; but then it may not be infinite. Indeed, we expect to find —recurring to the attitude of anticipation with which this notice began—we confidently expect to find in August next excellent reasons why the series should stop short at its third term. It is difficult to imagine how conditions for work could be bettered. Mount Wilson has great instruments and a fine climate; it has the financial backing of the wealthy Carnegie Institution; it is within easy reach of Pasadena, and in telegraphic communication with the whole world; and last, but by no means least, it has already an able staff of workers, including men like Adams, Ellerman, and Ritchey, whose names are famous wherever there is an astronomer. Those who have visited the mountain are enthusiastic in praise of the conditions for work. A notable visit was paid by Prof. Barnard, who found the times of exposure required for his photographs considerably less than at the Yerkes Observatory.

The main purpose of the Mount Wilson Observatory is solar research, but a wide interpretation must be given to the term. Prof. Hale has often emphasised the representative character of the sun—it is the one star near enough to be examined in detail; but it is nevertheless a star, and to understand it we must study it alongside other stars; we cannot do justice to the sun by working at the sun alone. Hence he has insisted on an adequate equipment for stellar work at Mount Wilson. The method of attacking scientific problems along more than one line is a characteristic feature of Hale's work generally, and has been an important factor in his success. To give a recent and striking instance. Along one line he was developing the spectroheliograph to the point where good photographs could be obtained in red light ($H\alpha$), and this led to the discovery of the solar vortices; along another line, which might have seemed irrelevant to the former, he was working at the photography of sun-spot spectra, and at last succeeded in getting good images of double and triple lines. Forthwith the two researches met and flowed in the same stream; to test the magnetic hypothesis of the vortices he could examine the spot spectra polariscopically. Had either of these two lines of work been neglected, the other would have remained unfruitful. No doubt there was an element of luck in the simultaneity with which the two became available; but luck proverbially attends on energy and enterprise.

H. H. TURNER.

THE BRITISH SCIENCE GUILD.

THE fourth annual meeting of the British Science Guild was held at the Mansion House on March 18, when the fourth annual report upon the work of the past year was presented. The Lord Mayor occupied the chair, and an address was delivered by Mr. Haldane, president of the Guild. Sir John Cockburn, K.C.M.G., gave a summary of the report, the adoption of which was moved by Lord Strathcona, and seconded by Sir Alfred Keogh, K.C.B. Sir George Darwin, K.C.B., and Sir Ernest

Shackleton also spoke. We propose to print the main parts of these speeches later, and here limit ourselves to the mention of a few points of wide interest included in the report.

The following gentlemen were elected as new vice-presidents:—Sir William White, K.C.B., F.R.S., Sir Clifford Allbutt, K.C.B., F.R.S., Sir George Darwin, K.C.B., F.R.S., Surgeon-General Sir A. Keogh, K.C.B., Right Hon. Sir George Reid, K.C.M.G. The following new members of the executive committee were also elected:—Sir David Gill, K.C.B., F.R.S., Sir William White, K.C.B., F.R.S., the Rt. Hon. the Earl of Chichester, Sir A. Keogh, K.C.B., Mr. A. Mosely, C.M.G., Sir Boverton Redwood, Colonel Sir John Young, C.V.O.

The executive committee proposes to offer two prizes for an essay on "The best way of carrying on the struggle for existence and securing the survival of the fittest in national affairs." The essay should state the main points to which attention must be directed; the following, in which the practice of modern nations differs, may be touched upon:—

(1) The training of the citizen to secure national efficiency in peace, and national defence in war.

(2) State organisations for securing the same objects.

(3) The State endowment of the higher teaching and research in universities and elsewhere.

(4) Whether a system of party government alone is sufficient to secure all the best interests of the State in those directions in which brain-power and special knowledge are needed, or whether a body free from the influence of party politics and on which the most important national activities are represented by the most distinguished persons is desirable.

(5) Whether it is of advantage that the nation's greatest men in science, learning and industry on whom, in peace, the prestige and progress of the nation chiefly depend should be in touch with the head of the State.

(6) How discoveries and applications of science can be best and soonest utilised for State purposes both in peace and war.

Formation of Colonial Branches.

In the last annual report reference was made to the proposed formation of branches of the Guild in Australia and Canada. During the year further progress has been made, and inaugural meetings have been held in Winnipeg (Canada) and Sydney (New South Wales). A branch is also being formed in South Australia.

In Canada an organising committee has been formed, consisting of the leading educational, scientific, and business men. By forming such a committee, it was considered that not the least of the advantages would be the keeping in touch with the scientific methods throughout the Empire, and it was hoped that the Canadian committee might thus be the means of obtaining accurately for the British Guild information on Canadian matters.

The inaugural meeting of the New South Wales branch was held on October 13, 1909, at the Royal Society's House, Sydney, the Governor of New South Wales, Lord Chelmsford, occupying the chair. In the course of an address Lord Chelmsford said that what is wanted to-day, and what he thought the Guild intends to try to do, is to get a scientific spirit to permeate the public at large. Science is an end in itself; but the general public should be convinced that in giving money for scientific purposes they are giving it for a good cause, and also that scientific knowledge is worth something in pounds, shillings, and pence. He hoped in that way to get the public alive to the importance of scientific knowledge in everyday life. Departments of public instruction may bring forward schemes of coordination and the like, but until the parents have been convinced that education is of value to them, all the schemes in the world are not going to make them

alive to education. In Germany and in America parents in the homes are alive to the importance of education, and they are determined to undergo any personal sacrifices if they can only give their sons and daughters the best possible education.

In the case of agriculture, we have to convince the farming community as a whole that there is something in scientific knowledge that is going to be of value to them. This is very hard to do. It is to be hoped that by its methods the Guild will be able to press home, not only upon men in authority—he believed men in authority are fully alive to the value of scientific knowledge—but also upon the men in the street, that scientific knowledge is not a mere abstraction, and that if devoted to commerce, trade, and everyday life, it will sweeten and enrich the lives of all and help the well-being of the community at large.

Speaking of the objects of the Guild, Dr. F. A. Bennet said that Germany spends more money on the University of Berlin alone than does England upon the whole of her universities put together. "It is not the German Dreadnoughts we have to be afraid of, but the German school-master," observed Sir James Graham. "He is the man who is doing the damage."

In South Australia, the Governor, Sir Day Hort Bosanquet, is acting as patron of the branch. In a circular, issued by the secretary, the ideals of the Guild are stated as:—

"To give one kind of education only to the people of the Empire—the best (both practical and theoretical)—and to secure its economic application to the wants of mankind."

"To help us to keep our Empire the greatest factor in the world and retain our immense commerce. To do this we must teach the people the necessity of applying the methods of science to all branches of human effort. It must be observed that practical and scientific knowledge combined, and its application to useful purposes, is the secret of all human mental influence and power. It reduces labour, increases pleasure, and gives health and contentment."

"Scientific straight-thinking is just as good for us as a navy is for Germany. Brains lie at the root of all things."

The Want of National Organisation.

The president of the Guild in his address last year remarked:—"The exertions of our people as a united people are necessary if we are to hold our own in the stress of the competition of nations." These remarks have led the executive committee to consider how best the suggested changes can be brought about. The committee points out that in the case of the armed forces of the country, following the example of Germany, a general staff for army purposes is already in being, and the Government has announced that a similar organisation is being established for naval purposes. The view that the peace purposes of the nation could be well served by an organisation dealing similarly with peace requirements, and indeed that they cannot be best served without it, is rapidly gaining ground, all the more because it is becoming fully recognised that party politics deal more with the temporary success of a party than with the permanent welfare of the State. A body composed of men selected from among the most eminent representatives of science, education, industry, commerce, and finance, associated with the technical heads of the Government institutions dealing specially with such matters, would provide such a general staff fully competent to deal with questions in which united action would be conducive to the nation's welfare and progress.

In university organisation there has been steady growth of opinion in two directions. First, the necessity for the fullest consideration of research in connection with all the higher teaching; and, secondly, the national loss which results from the exclusion of the universities from the Government view of education as represented by its Board.

In giving a statement of some scientific researches which have recently been aided by the State, the executive committee remarks that the present Government has shown itself more anxious to promote scientific inquiry than any of its predecessors.

Work of Committees.

New committees have been formed for dealing with the conservation of natural sources of energy, and to consider the question of technical education and its position in regard to universities. In addition to these, there are committees dealing with education, inexpensive instruments in science teaching, agriculture, synchronisation of clocks, naming and numbering of streets (executive committee), and the coordination of charitable effort.

The medical committee has been increased in numbers in order to take up specially the consideration of medical research. In its report this committee emphasises the very great importance of post-graduate medical study, and points out the very wide field and the great materials for such work which exist in London, and that owing to the absence of organised effort relatively little use is being made of this immense field. It is further considered that the ideal to be worked for is the establishment of a central medical school in connection with the London University, which should be devoted to post-graduate teaching and research. Such central school might be associated with all the London hospitals in connection with the London University for the purpose of post-graduate medical study, and should have affiliated to it other medical institutions and hospitals for the treatment of special types of disease (such as hospitals for epilepsy and diseases of the nervous systems, the Royal Ophthalmic Hospital at Moorfields, Brompton Hospital for Consumptives, &c.). Professors appointed by the Central London University School would be deputed to work at any of the appointed institutions, where special facilities might exist for research and post-graduate teaching in the subject dealt with by each professor. The committee is strongly of the opinion that much greater facilities should be given for medical research than exist at the present time, and that large funds should be furnished from public and private sources for such purposes. One of the objects on which expenditure is urgently required is in the endowment by the Central London University School of arrangements for pathological research at the medical schools.

The committee on the conservation of natural sources of energy, of which Sir William Ramsay is chairman, has decided to draw up reports on (1) coal, particularly in connection with its employment for smelting and other industrial purposes; (2) internal-combustion engines and oil engines; (3) atomic and interatomic energy; (4) the availability and quantity of natural oil and natural gas; (5) the heat of the earth; (6) availability of water-power; (7) forestry; (8) carburisation of coal at high and low temperatures; (9) solar power.

THE PROPOSED SCOTTISH NATIONAL ANTARCTIC EXPEDITION OF 1911.

A LARGE and enthusiastic meeting, organised by the Royal Scottish Geographical Society, was held in the Synod Hall, Edinburgh, on Thursday evening, March 17, to hear the plans of Dr. Bruce for his second Antarctic expedition. Prof. J. Geikie, F.R.S., president of the society, was in the chair, and was supported by a number of representatives of Scottish scientific bodies and others. The keynote of the meeting was that the aim of the expedition was to be throughout scientific. This was emphasised first of all by the chairman, who on that ground disclaimed the idea against which a needless protest had been put forth by the president of the Geographical Society of Berlin, that Antarctic exploration should be in any way reserved for any particular nation, and, in view of the immense field for scientific investigation in Antarctica, welcomed the friendly rivalry of all nations in carrying out that work.

Dr. Bruce then addressed the meeting, and before giving an account of his present plans, gave a brief sketch of the history of Antarctic exploration, laying special stress on the part that Scotsmen had borne in that work since Weddell set sail from Leith in 1823. It is hoped that the expedition now planned will leave Scotland about May 1, 1911, and reach

Buenos Aires about June 20 of that year. About ten days later it will sail for Cape Town, pursuing a zigzag course, for the most part, between the parallels of 40° and 50° S., but including a visit to the Sandwich group in about 57° S., as well as to Gough Island. The purpose of this navigation will be to supplement the bathymetrical survey of the South Atlantic Ocean begun by the *Scotia* in 1902-4, and it is not expected that Cape Town will be reached before September 1. After refitting and coaling, the ship will sail once more for the Sandwich group, and thence to Coats Land, and seek for a place on or near that coast where it may be possible to land and erect a house, although from the experience of the previous expedition it is thought possible that it may be necessary to go so far east as Cape Ann in Enderby Land for that purpose. At some point in Coats Land, however, it is intended that a sledge-party of three, under the leadership of Dr. Bruce, shall land with the view of crossing to the Ross Sea by way of the South Pole. The ship, after landing a party of ten or twelve persons at whatever point they find suitable for the erection of a house, will proceed, by a route in as high a latitude as possible, to winter at Melbourne, taking soundings and carrying on deep-sea research all the way.

In the following spring the ship will leave Melbourne and push southward to McMurdo Strait, Victoria Land, in order to send a sledge party to meet, and furnish with fresh supplies, the previously landed sledge-party under Dr. Bruce. It is expected that the two parties will meet near the Beardmore Glacier, and, after meeting, the combined party will proceed to the ship and sail for New Zealand. Further oceanographical work will afterwards be carried on between New Zealand and the Falkland Islands in as high a latitude as the winter season will permit, and in the following spring the ship will sail southwards to relieve the wintering party, which by that time will have been engaged for two years in surveying the coast-line of Antarctica east and west of the station, and in taking meteorological, magnetic, and other observations. The total cost of the expedition is estimated at about 50,000*l.* Dr. Bruce, it may be mentioned, is in cordial correspondence, not merely with Captain Scott, but also with the promoters of the German expedition, and there is good reason to hope that if funds are raised both for his and the German expedition, there will be no useless overlapping of work. As regards the McMurdo Strait, which Captain Scott has chosen for his special sphere of work, Dr. Bruce expressly announces that the Scottish expedition will make no special investigations in that region.

The meeting was then addressed by Dr. John Horne, F.R.S., director of the Geological Survey of Scotland, who, as representing the Royal Society of Edinburgh, first referred to the high value of the publications already issued giving the scientific results of Dr. Bruce's previous Antarctic expedition, including upwards of twenty papers published by the society he represented, and expressed the hope that the Government would see its way to furnish the necessary funds for the publication of the remaining results, which were eagerly looked for by all interested in Antarctic exploration in every part of the world. He stated that he was commissioned by the council of the society to give to Dr. Bruce's new scheme the most cordial recommendation to the Scottish public for financial assistance.

Prof. J. Graham Kerr, F.R.S., professor of zoology in the University of Glasgow, then spoke as representative of the Royal Philosophical Society of Glasgow, expressing that society's cordial sympathy with Dr. Bruce's project, and especially because they felt that they had in him a splendid example of the type of explorer who, while ready to take any adventures that came his way, recognised that his real object was to do honest scientific work. The Earl of Cassilis, representing the St. Andrew Society, dwelt

more particularly on the contrast presented by the large grants that had been made by Government to other Antarctic expeditions, and the entire lack of recognition, so far, of the work of proved value that had been done by Dr. Bruce.

Prof. J. Cossar Ewart, F.R.S., professor of zoology in the University of Edinburgh, then commented on the zoological value of Dr. Bruce's expeditions, which had been the means of adding dozens of new species to scientific knowledge, and on that account gave his cordial support to the carrying out of this second Scottish Antarctic Expedition. In an eloquent speech Prof. D'Arcy W. Thompson, C.B., of the Scottish Fishery Board, professor of zoology in University College, Dundee, expressed warm appreciation of the work that Dr. Bruce had already done in his previous expeditions. Mr. Chisholm, lecturer on geography, Edinburgh University, recommended Dr. Bruce's plans to the support of the meeting, among other grounds, on account of the fact that Dr. Bruce had shown his qualifications as a leader by the attachment and devotion which he inspired in his followers, and this point was immediately enforced by Dr. R. N. Rudmose Brown, lecturer on geography in the University of Sheffield, who had accompanied him in expedition after expedition.

At the close of the meeting, on the motion of Mr. W. G. Burn-Murdoch, a resolution asking the meeting, as a representative Scottish gathering, to express their hearty desire to have Dr. Bruce's plans carried out, was unanimously approved. It should be added that, while the opinion that it was the duty of the Government to contribute to the publication of the results of the *Scotia* expedition was very freely expressed at the meeting, the appeal for funds to carry out the present projected expedition is not made, in the first instance at least, to the Government, but to "the enthusiasm and patriotism of Scots at home and abroad."

PROF. J. CAMPBELL BROWN.

AS recorded with regret last week, Prof. James Campbell Brown, professor of general chemistry at the University of Liverpool, died very suddenly from heart failure on Monday, March 14. Prof. Campbell Brown, who was the son of the late Mr. George Brown, a chemical manufacturer with a business in London, was born in Aberdeenshire in 1843. He studied at the University of Aberdeen, and afterwards at the Royal College of Chemistry and the Royal School of Mines, London. He was a D.Sc. of London University, and LL.D. (*honoris causa*) of the University of Aberdeen. His connection with Liverpool began in 1867, when he was appointed lecturer in chemistry and toxicology at the Royal Infirmary School of Medicine. He became public analyst for Liverpool in 1872, for Cheshire and the Isle of Man in 1873, and for Lancashire in 1875. In 1877, being then chairman of the Royal Infirmary School of Medicine, he took a prominent part in the movement for the foundation of a university college in Liverpool, and from 1878 to 1884 was one of the secretaries of the special committee which afterwards became the council of the new college. Prof. Campbell Brown may, therefore, rightly be said to have been one of the prominent founders of the present University of Liverpool. In 1881 he was appointed to the chair of chemistry endowed by Mr. Grant, of Rock Ferry. When death overtook him he was still the active occupant of this chair.

For more than forty years Prof. Campbell Brown exercised an important and beneficial influence on higher education, and especially higher scientific education, in this country. In Liverpool in particular he developed a flourishing department of chemistry, and was very successful in enlisting the

sympathy and obtaining the aid of the chemical manufacturers of Lancashire and Cheshire. As a public analyst of experience and repute he did much for the improvement of our methods of suppressing the falsification and adulteration of foods and drugs.

In 1874 he published a report on the chemistry of tea cultivation in India, and made important recommendations which proved of great value to that industry.

He contributed a very considerable number of papers to the scientific journals, and was awarded two gold medals by the Franco-British Exhibition. In this connection his excellent work on the latent heats of evaporation of liquids deserves special mention. Quite recently he contributed a paper to the Chemical Society dealing with double and triple ferri-cyanides.

In 1908 he was elected a vice-president of the Chemical Society. A man of genial, kindly, and unselfish nature, his heart was entirely in the work to which his life was devoted. He lived to see his labours crowned with a well-deserved success. The University of Liverpool owes him a debt of gratitude which few can appraise, and it stands to-day a memorial of his wisdom and foresight, his marvellous power of organisation, and his profound belief in the value of the investigation and dissemination of knowledge and truth.

F. G. D.

NOTES.

SIR WILLIAM RAMSAY, K.C.B., has been nominated "Membre d'Honneur"—honorary member—of the Chemical Society of France.

SIR THOMAS BARLOW, F.R.S., has been elected president of the Royal College of Physicians, London, in succession to Sir Richard D. Powell.

THE Aldred lecture of the Royal Society of Arts will be delivered by Prof. H. H. Turner, F.R.S., on Wednesday, May 4. The title of the lecture is "Halley and his Comet."

THE death is announced, in his seventy-second year, of Dr. Otto Hermes, founder of the Berlin Aquarium. Dr. Hermes was appointed director of the aquarium in 1871, and was known by his writings on zoological subjects.

AMONG the latest developments of Germany's airship movement we notice the fund raised by Prince Henry of Prussia for the building of a dock at Hamburg capable of housing at least two Zeppelins. Of the 50,000l. required, 20,000l. was raised almost immediately.

A YOUNG horn of *Cervus megaceros* has been dug up recently from a depth of 2 or 3 feet below the surface of Martin Mere, near Southport, in Lancashire. It is the property of the Rev. Mr. Bulpit of that town, by whom the specimen has been submitted for determination to the director of the Liverpool Museums.

THE following awards of the Royal medals and other honours have been made by the council of the Royal Geographical Society:—Royal gold medals: founder's medal, Colonel H. H. Godwin Austen, C.M.G., F.R.S.; patron's medal, Dr. W. S. Bruce; Murchison grant, Dr. Carl Skottsberg; Gill memorial, Mr. D. Carruthers, for his journey in north central Arabia; Cuthbert Peek grant, Lieut. C. E. Fishbourne, R.E.; Back bequest, Mr. H. Vischer. A special medal has been awarded to Rear-Admiral Peary for his attainment of the North Pole.

By the death of Prof. J. Edmund Wright, of Bryn Mawr College, a young mathematician of great promise has been lost. Prof. Wright graduated at Trinity College, Cambridge, being senior wrangler in 1900, subsequently taking a first in "part two" and obtaining a Smith's prize. He was in 1903 appointed associate professor in Bryn Mawr College, in succession to Prof. Harkness. He was the author of a "Cambridge Tract" on "Invariants of Quadratic Differential Forms," and he also wrote on theory of groups, differential geometry of space, and Abelian functions.

SIR FREDERICK MAPPIN, BART., whose death at the age of eighty-nine years took place on March 19, was an active friend of higher education in Sheffield. He took a very prominent part in founding the Sheffield Technical School, which later formed an important part of the University College, and is now merged in the University of Sheffield. He contributed generously towards the support of these institutions, and at the time of the foundation of the University gave 15,000*l.* to its fund. He was one of the first two Pro-Chancellors of the University, and was also chairman of its department of applied science.

An International Hygiene Exhibition is to be held in Dresden next year. At a meeting of members of the British executive committee of the exhibition, held on March 16 at the Hotel Cecil, Prof. Pannwitz, the deputed representative of the scientific department, delivered an address. He explained the aims and objects of the exhibition, the support which is being extended by the German Imperial and State Governments, the efforts which many civilised countries are making to secure an effective representation, and he concluded by expressing his full confidence that the British representation will be in every respect worthy of the country which is the acknowledged birthplace of sanitary science. Offices are to be opened in Victoria Street, S.W., for the accommodation of the British executive and for the general working of the undertaking in this country.

THE sixty-third annual meeting of the Palæontographical Society was held at Burlington House on Friday, March 18, Dr. Henry Woodward, F.R.S., president, in the chair. The report of the council referred to the progress of the monographs on Pleistocene Mammalia, Cretaceous and Carboniferous fishes, and Cretaceous Lamellibranchia, and recorded the gift of a series of plates of Carboniferous fishes by the Carnegie Trust for the universities of Scotland. It lamented the death of two members of council during the past year, the Rev. G. F. Whidborne and Mr. C. Fox-Strangways. Miss M. S. Johnston, the Rev. R. Ashington Bullen, Dr. F. L. Kitchin, and Mr. A. W. Oke were elected new members of council. Dr. Henry Woodward, Dr. G. J. Hinde, and Dr. A. Smith Woodward were re-elected president, treasurer, and secretary respectively.

FROM the *Deutsche Zeitschrift für Luftschiffahrt* we learn with deep regret of the death of the founder and editor of that journal, Lieut.-General H. W. L. Moedebeck. The name of Moedebeck figures prominently in the annals of German aeronautics, and even the published records which reach this country afford evidence of the powerful influence of his personality in stimulating aeronautical enterprise. He is described as a man possessing ideas, not only for the requirements of the day, but for developments of the future. Before airships were thought of he devised methods of preventing explosions in motors, and his geographical surveys were also initiated, in the face of con-

siderable opposition, before the demand for them had arisen in connection with aerial navigation. In 1884 he was first appointed by the German Government to develop the balloon for military purposes. He has published a handbook and a pocket-book of aeronautics, of which the latter is now well known in this country. His works on "Airships: their Past and Future," and on flying men, have done much to popularise aeronautics; but perhaps the two things which stand out most prominently as his life-work have been the *Deutsche Zeitschrift* and the aeronautical map brought out in connection with the above-mentioned survey. The part which Moedebeck played in developing the "Zeppelin movement," especially at a time when the Count had few supporters, is also worthy of note.

NEARLY thirty years ago, the sanction of Parliament was given to a scheme to obtain an adequate water supply for Liverpool from the Welsh hills. This undertaking was completed on March 16, when the Prince of Wales visited Lake Vyrnwy and turned on into the great artificial lake there the water collected from the Marchnant River. The complete scheme for the water supply of Liverpool outlined by Messrs. G. F. Deacon and T. Hawksley comprised the impounding of the rivers Vyrnwy, Marchnant, and Afon Cownwy. The two latter are higher than the former, and the work in connection with them was carried out after the Vyrnwy scheme was finished. In the cases of Afon Cownwy and Marchnant the rivers were dammed, and tunnels cut through the intervening hills so that the impounded water could empty itself into the Vyrnwy. The Afon Cownwy tunnel was 7 feet in diameter and 6723 feet in length, and the Marchnant tunnel 7 feet in diameter and 7345 feet in length, and it was at the latter one that the Prince of Wales opened the valve which allowed the water to flow through the tunnel into the Vyrnwy lake, thus completing the whole scheme. The completed scheme as it now stands has a gathering ground of 22,742 acres, and the capacity of Vyrnwy lake is 12,131 million gallons; its greatest depth is 84 feet; the area of its surface is 1121 acres, and its length 4½ miles. The surface-level of the lake above the sea is 825.89 feet Ordnance datum, and the level of the highest point in the watershed is 2050 feet Ordnance datum. The water engineer of Liverpool, Mr. Joseph Parry, has been entirely responsible for the work in connection with the Marchnant and Afon Cownwy rivers.

THE last Bulletin, that for March 10, of the Institution of Mining and Metallurgy contains the annual report of the council, which deals with the work of the year 1909. The gold medal of the institution has been awarded to Prof. William Gowland, F.R.S., in recognition of his services in the advancement of metallurgical science and education during a long and distinguished career. "The Consolidated Gold Fields of South Africa, Ltd.," gold medal has been awarded to Mr. W. A. Caldecott, in recognition of his work in the investigation of methods of reduction and treatment of gold ores and of his contributions to the literature of the subject. "The Consolidated Gold Fields of South Africa, Ltd.," premium of forty guineas has been awarded conjointly to Messrs. C. O. Bannister and W. N. Stanley, for their work in the investigation of the thermal properties of cupels, and for their joint paper on "Cupellation Experiments—the Thermal Properties of Cupels." Four post-graduate scholarships, each of 50*l.* in value, have been awarded. The total membership of the institution at the end of the year under review was 1902, which represents an actual increase of 277 in two years.

GERMAN geology has sustained a serious loss by the death of Dr. Emil Philippi, extraordinary professor of geology at Jena, who is best known as the geologist with the German Antarctic Expedition under Prof. von Drygalski. He had been from 1901 to 1906, except during his absence with that expedition, a privat-docent in Berlin. In 1906 he was called to Jena to succeed Prof. J. Walther as assistant to Prof. Lenck. Dr. Philippi will be best remembered by his contributions to the geology of the Gaussberg, beside which the *Gauss* wintered in the Antarctic; they and his memoir on the islands visited on the voyage have been reviewed in NATURE. His other contributions are mainly on problems connected with glacial geology. He was especially interested in faceted stones, which he discovered both in the drifts of north Germany and in Antarctic icebergs. He seemed disposed to regard faceted stones in general as due to ice work. He published in 1908 a short memoir on the Upper Palæozoic glaciation of southern Africa and Australia, for which he accepted a Permian date. He accompanied the Geological Congress in its excursion to Mexico in 1906, and subsequently wrote an account of the tectonic effects of the intrusion of the syenite porphyry of Cerro Muleros. His premature death in Egypt has cut short a career of great promise.

THE Premier (Transvaal) Diamond Mining Company recently presented to the British Museum (Natural History) an interesting series of specimens from the Premier Mine, near Pretoria. The examples of diamondiferous rock which come from different depths, ranging from 15 to 160 feet below the surface, exhibit very clearly the change that takes place in the colour and texture as the depth increases; the specimen, orange in colour and powdery in character, which came from the shallowest depth, is in marked contrast with that, bluish and hard, which was taken from the lowest depth. The series of rough diamonds, eighteen in number, and nearly 9 grams, or 29 carats, altogether in weight, gives an idea of the variation possible in the form, transparency, and colour of the stones found in the mine; thus there are a clear white octahedron and a black opaque boart, a tetrakis-octahedron, nearly spherical in shape, and a flat, triangular twin, and yellow, pink, and brown stones. Examination in polarised light shows that most of the diamonds are in a state of strain. A specimen of "blue ground" out of which emerges a diamond is of especial interest, because it so rarely happens that the rock is split just where a diamond chances to be. The series includes also specimens of the associated minerals, pyrites, calcite, and "Cape-ruby" (pyrope-garnet).

GREAT efforts are being made by the committee, of which Lord Desborough is chairman and Mr. C. E. Fagan secretary, to render the British big-game section at the forthcoming Vienna Sports Exhibition a success. His Majesty the King, who has given directions that the skeleton of his famous thoroughbred Persimmon should be sent, is taking great personal interest in the matter; and the trustees of the British Museum have placed the services of a portion of the staff of the Natural History Branch at South Kensington at the disposal of the committee. One of the special objects of this section is to exhibit a representative series of trophies of the big-game animals found in the British Empire (inclusive of protected States). The number of such species, according to a provisional list drawn up for the committee by Mr. Lydekker, is about 165, but many of these are represented by two or more local races. A number of sportsmen and other owners of trophies of this nature have been asked to lend specimens, especially

those approaching or representing the "record," and the replies have been, on the whole, of an encouraging nature, the names of those who have promised to lend specimens including the King, the Prince of Wales, the Duke of Westminster, Lord Lansdowne, Mr. Chas. Lucas, and a number of well-known big-game sportsmen. It is also intended to exhibit specimens of the game mammals, birds, and fishes of the British Isles. A photograph of the picturesque building intended for the reception of the British trophies appears in the *Field* of March 19, accompanying a letter from Lord Desborough. The main difficulty is the shortness of the time available, the exhibition opening in May.

WHEN the Aërial League was founded, an excellent opportunity was afforded to the British public to retrieve the reputation implied in the words "England's Neglect of Science"; but in an article in the *Standard* (March 14) Captain Cave Browne Cave draws a striking comparison between the support which this movement has obtained and the reception accorded to similar efforts abroad. He says:—"In Germany up to last year the public had subscribed 330,000*l.* towards the building of an aërial fleet. The Government has made grants amounting to 250,000*l.* The Aërial League, founded in 1908, has attained a vast membership; a practical school of aëronautics has been founded at Friedrichshafen, and a chair of aëronautics at Göttingen University; the wharves, docks, aluminium foundry, hydrogen factory, and large construction yards which have been built at Friedrichshafen are capable of turning out six complete Zeppelins annually, while the output of Gross, Parseval, and other equally successful types of military dirigibles is practically unlimited. In France Government lands have been placed at the disposal of pioneers of flight; great public subscriptions have been raised. Prominent men like Messrs. Deutsch, de la Meurthe, Basil, Zaharoff, and Archdeacon have come forward from time to time with munificent gifts, aggregating over 100,000*l.*, for the foundation of aërotechnical institutions, for scientific research work and tuition in aëronautics, for special prizes and the encouragement of inventors. A college of advanced aëronautics has been inaugurated at Paris for the theoretical and practical training of aviators. The French Aërial League, with a membership well over 10,000, has courses of study and practical work at its Juvisy flying ground. In England the Aërial League has been formed, but the appeal to the British people has produced little result."

WE regret to record the death, on March 6, of Mr. Charles Fox-Strangways. Born in 1844 at Rewe, near Exeter, where his father, a grandson of the first Earl of Ilchester, was rector, Mr. Fox-Strangways was educated at Eton and afterwards at Göttingen, where he studied mineralogy, chemistry, and physics. In 1867 he was appointed an assistant geologist on the Geological Survey under Murchison, and was engaged for some years in mapping parts of the Yorkshire coal-field, the country around Harrogate, and a large area extending across the Vale of York to the Jurassic and Cretaceous rocks of the east Yorkshire moorlands, and the coast near Scarborough. He was author, or part author, of several memoirs, notably one on the geology of Harrogate, of which a second edition was published in 1908. His chief publication was a general memoir on the Jurassic rocks of Yorkshire, published in two volumes, 1892. In 1889 Mr. Fox-Strangways was transferred to the Midland district, residing for many years at Leicester while engaged in surveying the Leicestershire coal-field and bordering areas. He was author of

memoirs on that coal-field, and on the country around Derby, Burton-on-Trent, Atherstone, Charnwood Forest, and Leicester. In 1901 he was promoted to be district geologist, but retired from the public service in 1904, as a weakness of the heart, which ultimately proved fatal, rendered it necessary to give up the arduous work of a field-geologist. His geological labours, represented by official maps, sections and memoirs, and by papers communicated to scientific societies, bear evidence of the most painstaking care and accuracy. While at Leicester Mr. Fox-Strangways did much to promote local interest in geology, especially by conducting field-excursions, which were highly appreciated.

ACCORDING to a telegram from Paris in the *Times* of March 13, an International Congress for the Study of Cancer will be held in that city, under the patronage of the President of the Republic, in the first week of October. The assemblage will not be a congress in the true sense; its official title is "Second International Conference for Cancer Research," the first meeting of the kind having been held in Heidelberg in 1906, as the outcome of which a sort of international association has developed. From this association, however, British investigators have hitherto held aloof, notwithstanding efforts that have been made from Berlin to induce the Imperial Cancer Research Fund—which is the national and representative body in this country—to join. These efforts have taken the form of questions addressed to the Prime Minister in the House of Commons, and even went so far as the presentation of a petition to the King during his visit to Berlin in February, 1909. The German organisers of the so-called international association have used their best efforts to have the first International Congress on Cancer held in London in 1910; but this proposal was discountenanced by the director of the Imperial Cancer Research Fund, Dr. E. F. Bashford, and the executive committee, on the ground that the time for such a congress had not yet arrived. It was felt that such a congress held in London under the auspices of the Imperial Cancer Research Fund, backed as it is by the support of various Government departments, the Royal Society, the Royal Colleges of Physicians and Surgeons, and other public bodies, would arouse too great expectations on the part of the public. The programme for the forthcoming meeting in Paris covers a wide range of subjects, but in the absence of the names of those contributing papers it is too early to decide what importance will attach to the assembly. The list of office bearers given in the *Times* exhibits the remarkable feature of not including a single name of an active worker in those fields of cancer research which are the direct contributors to the success attending the investigations of the past ten years. However distinguished some of these names are in the realms of practical medicine and surgery, they add little, if any, weight to the purely scientific side of an assembly called together to study so recon-dite a problem as cancer.

DR. LUIGI PERNIER, under the title of "Vestigia di una Città Ellenica arcaica in Creta," has issued, through the Istituto Lombardo di Scienza e Lettere, an account of a summary examination of an early Greek city in Crete. It is surrounded by walls of cyclopean masonry, now partially ruined. Some inscribed stones and terra-cottas were discovered, the most interesting find being a stele representing a standing figure facing to the right, clad in a tightly folded robe, and holding in the left hand something resembling the Egyptian Ankh. The figure possibly shows the influence of Minoan traditions, and the site clearly deserves further detailed examination.

MAJOR LAMB, I.M.S., and Captain McKendrick, I.M.S., detail certain observations on rabies in the Scientific Memoirs of the Government of India (No. 36). They find that when the "natural" virus is passed through dogs a "fixed" virus is obtained just as with rabbits, and that the structures known as "Negri bodies," while easily demonstrable in the natural virus, cannot be found in the fixed virus. In several cases, both in dogs and in rabbits, a chronic form of rabies was observed, the chief symptom of which was progressive emaciation. It is comparatively easy to infect guinea-pigs and monkeys by subcutaneous inoculation of the virus. As in monkeys the incubation period is much prolonged when the inoculation is subcutaneous, attempts were made to immunise these animals with a single subcutaneous inoculation with a fixed virus, but without success. No bacteriolytic properties towards the virus could be detected in the serum of patients who had undergone the anti-rabic treatment.

FISHERIES, IRELAND, SCI. INVEST., 1908, iv. (1910), is devoted to an account, by Messrs. E. W. L. Holt and L. W. Byrne, of the chimæroid fishes of the Atlantic slope off the west coast of Ireland. The most interesting of these is *Rhinochimaera atlantica*, a long-beaked species known by a single adult male captured at a depth of between 670 and 770 fathoms, and certain egg-capsules attributed to the same species, which was first named by its describers in 1909. *R. atlantica* belongs to a genus otherwise represented by *R. pacifica*, distinguished by the relative shortness of the base of the second dorsal fin. The only Atlantic chimæroid with which *R. atlantica* could be confounded is *Harriotta raleighana* of the western Atlantic; the largest of the four known specimens of the latter is, however, not more than half the size of the type of the former, which, in turn, is decidedly smaller than its Pacific representative. *Harriotta* is also otherwise distinguished.

In the thirteenth quarterly report on the scientific work of the Lancashire and Western Sea-fisheries, Mr. J. Johnstone refers to experiments carried out at Conway in regard to the cleansing of mussels from sewage-pollution. By transplanting the mussels to pure water, about 90 per cent. of the sewage-bacteria was eliminated, from which it appears that it will be possible to render the polluted molluscs of the Conway estuary fit for human consumption at a comparatively small cost. In the fourteenth report Mr. Johnstone dwells on the measurements of plaice which have been made during the last two years, these relating to something like 100,000 individual fish. These lead to the provisional conclusion that, in spite of the enormous numbers of under-sized fish taken by this method, the 6-inch trawl-mesh is not harmful to the plaice-fishery. "The plaice are small and below the normal in 'condition' because they are so abundant. If they could be 'thinned out' by transplantation it might be of advantage to the fisheries in general to enforce the 7-inch mesh; but so long as they cannot be transplanted I do not think that the use of the larger mesh would lead to any improvement, and it would certainly diminish the takings of the inshore fishermen."

VARIOUS attempts have been made from time to time to interpret the phenomena of sex-determination in accordance with Mendelian principles. The problem is again attacked by Mr. Geoffrey Smith in the first of his "Studies in the Experimental Analysis of Sex," published in the *Quarterly Journal of Microscopical Science* for February. Some years ago this investigator was led to formulate a Mendelian interpretation of sex-inheritance as a result of his remark-

able observations on the parasitic castration of the crab *Inachus* by the degenerate barnacle *Sacculina*. Male crabs when infected by the parasite develop the secondary sexual characters of the female, and in certain circumstances ova may actually appear in the gonad. Female crabs in like case, however, do not develop male characteristics. Hence it was concluded that the male crab is a potential hermaphrodite, in other words, a heterozygote in which, under normal conditions, maleness is dominant. The female crabs, on the other hand, were regarded as pure recessives in respect of their femaleness. On these facts, amongst others, the author bases his "half-hybrid" theory of sex-inheritance, in accordance with which one sex is a heterozygote showing dominance of maleness or femaleness, while the other is a pure recessive homozygote. It appears that Prof. Bateson and Mr. Punnett two years later arrived independently at the same result in endeavouring to interpret Doncaster's remarkable breeding experiments on the currant moth, but in this case the female is the heterozygote and the male the homozygote. Mr. Smith also deals with the correlation between primary and secondary sexual characters, again largely as a result of his own observations on the parasitic castration of *Inachus*. He concludes that the development of the secondary sexual characters is not primarily dependent on the gonad, but that the development of both is dependent upon a common factor, which is supposed to be a hypothetical "sexual formative substance," an internal secretion, occurring in two varieties, male and female. The theory, however, is somewhat complicated by the necessity of taking into consideration the well-known effect produced by the gonad on the development of the secondary sexual characters, as shown by castration. Mr. Smith's views on the question approximate closely to those of Mr. Walter Heape.

A CURIOUS abnormality in a batch of crocus specimens is described in the *Gardeners' Chronicle* (February 26). Some of the thin scale leaves that envelop the bud had developed into white fleshy leaves, which grew nearly as high as a normal flower, while the enclosed foliage leaves and flowers were stunted. It is suggested that the sap had been diverted to the scale leaves as a result of forcing treatment.

THE treatment of felled trees with the view of reproduction by coppice shoots forms the subject of an article in the *Indian Forester* (December, 1909). In Europe it is usual to cut the stumps flush with the ground. When this method has been followed in India, at any rate in the case of the well-known *sál* tree, *Shorea robusta*, coppice shoots are in many cases not formed at all; it appears that, owing to contraction, the wood and bark separate, and the dormant buds are not rejuvenated; but if a few inches of the stump are left, coppice shoots are abundantly produced.

WITH regard to the ultimate reasons for the injurious effects produced in plants by frost, an instructive article appears as an editorial in the *Gardeners' Chronicle* (February 19). It has been shown that ice is first formed in the interspaces between the cells, with the result that water is withdrawn from the cell sap; continued formation of ice causes disruption of the tissues; but ice-formation is not regarded as the chief cause of injury. A new theory receiving the approval of competent authorities has been advanced by the Swedish botanist Lidfors. He examined a number of plants such as *Cerastium* and *Viola*, which, without any apparent means of protection, survive the severe winters of Sweden, and found that

during winter the starch in the leaves was replaced by sugar. He then falls back on experiments connected with the maintenance of proteins in the cell sap and protoplasm, by which it has been shown that if water be extracted from the cell the proteins pass out of solution, causing destruction of the cell; but if sugar is present the proteins will remain in solution until a much lower temperature is reached. This theory also affords a logical explanation of the disastrous effects of spring frosts.

THE official forecast for the wheat crop of South Australia is now published in the *Journal of Agriculture* for that colony, and is put at 11½ bushels per acre. If this is realised it will be the second highest yield during the last twenty years. The average yield in 1893 was 7.5 bushels per acre; it fell steadily until 1896, when it was only 1.4 bushels, but then it rose slowly to 11.3 bushels in 1905 and has remained round about this figure since. The 1908 crop of 11.45 bushels was the highest on record. The yield for the United Kingdom in 1908 was 32.3 bushels.

It occasionally happens that milk which has stood at low temperature for twelve to twenty-four hours becomes so viscid that it can be drawn out into strings. The trouble is caused by a micro-organism, but as it is not very common no large number of investigations have yet been made. A case that arose in Rhode Island was fully investigated by Messrs. Cole and Hadley, the results being published as Bulletin 136 of the Rhode Island Agricultural Experiment Station. From the details given it appears that the organism resembles the *Bacillus lactis viscosus* described by Adametz and A. R. Ward, and belongs to the same group.

MR. H. T. FERRAR contributes further notes on the movements of subsoil waters in Egypt to the December (1909) number of the *Cairo Scientific Journal*. These deal specially with the variations of level observed in a number of experimental tube-wells specially set up in the province of Gharbia, in Lower Egypt, which indicate that the conditions in Lower Egypt are almost the reverse of those which obtain in Upper Egypt, the minor factors in the latter becoming the controlling factors in the former. A series of diagrams shows the relation of the Nile flood to the movements of water-table, with the modifications produced by such factors as the nature of the soil, seepage, and irrigation.

CAPTAIN TIXIER, of the Siam Indo-China Boundary Commission, contributes to *La Géographie* (xx., No. 6, p. 337) a valuable note on the orography of French Indo-China. The region may be described generally as a vast sandy plateau, uplifted towards the east and enclosed by four folds in parallel pairs perpendicular to each other. On the north the Tonkin and northern Annam fold runs north-west and south-east, with a parallel member, much less important, to the south, in the Cardamom range. At right angles to these, in a direction N. 25° E., are the Cape Varela-Poulo Condore chain and the great fold which appears to have rested its whole weight on the sand plateau, causing it to sink, and in balancing to rise to the east, the movement being accompanied by fracture in two directions parallel to the enclosing chains. The Gulf of Siam, with its almost uniform depth of 45 metres, is apparently a plain similar to that of Grand Lac and the Semoun.

WE have recently received an excerpt from the Bulletin of the Society of Historical and Natural Sciences of the Yonne (2 Semestre, 1908), consisting of a very useful

and laborious compilation by M. Ernest Blin of *Remarques météorologiques* made in various districts of that department between the fifteenth and eighteenth centuries. The notices are taken from the archives of various institutions and from provincial publications, and are arranged in chronological order, with references to the sources of origin, and furnish much information on the general character of the seasons and on conspicuous meteorological occurrences, floods, &c. Some interesting references are also made to the former practice of ringing church bells with the idea of dispersing hail and thunderstorms; this practice was still in vogue at Quarré-les-Tombes until the middle of the nineteenth century. The publication of this summary is due to a suggestion by M. E. Lauda, of the Austro-Hungarian Hydrographical Service, and recommended by the Meteorological Conference at Innsbruck in 1905, that all available historical documents of different States regarding abnormal weather phenomena should be collected and published.

In November last Mr. J. W. Giltay and Prof. M. de Haas communicated to the Koninklijke Akademie van Wetenschappen te Amsterdam an interesting paper, a copy of which has just reached us, on the motion of the bridge of the violin. Various statements as to the nature of the movement have been made by writers on acoustics, such as Helmholtz, van Schaik, Apian-Bennowitz, Barton, Garret, and Pentzner, but, by ingenious experiments, Giltay and de Haas have conclusively proved that the motion of the bridge is in two directions, namely, (1) in its own plane about one of the feet and at right angles to the strings, and (2) at right angles to its plane, or transversely, that is, in the same direction as the strings. The sound of a violin must be attributed to three causes:—(a) a vibration imparted to the air by the string; (b) a vibration which the roof of the violin receives from the parallel swing of the bridge; and (c) a vibration communicated to the roof by the transverse vibration of the bridge. The (a) movement may be left out of account as being very weak, and the intensity and timbre of the note is determined by the parallel and transverse motions, and more especially by the latter. Each of these motions has its fundamental tone and associated partials, and the quality of the tone is modified when the intensity of one of the motions alters its partials, while it may leave the other motion unchanged or slightly changed. A "mute" damps the transverse motion of the bridge to a higher degree than the parallel motion, and the use of the mute does not weaken intensity so much as to alter quality.

THE February number of the Johns Hopkins University Circular consists mainly of notes from the physical laboratory of the University, edited by Prof. J. A. Ames. One of the most interesting of the notes is that of Mr. J. A. Anderson, on a method of testing screws intended for the most accurate work, such as the ruling of diffraction gratings. A nut which fits the screw accurately is cut in two by a plane through its centre perpendicular to its axis, and the two parts rotated through an angle of 180° , for example, with respect to each other. One of the plates of a Fabry and Perot interferometer is mounted on each half of the nut, and the motion of the interference fringes observed as the screw is rotated by hand at a convenient speed, the two parts of the nut being prevented from rotating with respect to each other. The method is more sensitive than that of the late Prof. Rowland, which consisted in ruling two sets of grating lines at a small angle to each other and observing the loci of the intersections of the two series of lines.

THE *Electrician* for March 4 contains a short article by Dr. W. H. Eccles on the radiation from directive aërials in wireless telegraphy, in which the problem is treated by the exponential method, which has done so much to shorten the mathematical work in modern treatises on light. If the disturbance at the point of observation due to an aërial at a distance x is represented by $re^{i(u+x+a)}$, where u is a linear function of x and of the time, that from another aërial at a distance d from the former in a direction which makes an angle ϕ with the line joining the point of observation to the first aërial can be represented by a similar expression, with r and a omitted and u decreased by $2\pi d \cos \phi / \lambda$. The total disturbance at the point of observation due to the two aërials can then be represented by $e^{iu}(re^{ia} + e^{-i2\pi d \cos \phi / \lambda})$. The energy received is the square of the modulus of this, that is,

$$r^2 + 1 + 2r \cos(a + 2\pi d \cos \phi / \lambda).$$

This expression, plotted as a function of ϕ , gives the polar diagram of the directive system, the form of which depends greatly on the value of $2\pi d / \lambda$. The directions in which the radiation from the aërials is a maximum for a given value of a , the relative phase, are independent of r , the ratio of the amplitudes of the oscillations in the two aërials.

ALTHOUGH users of glass apparatus are familiar with the general appearance of the breaks which sometimes occur, no one has hitherto made a scientific study of their forms in relation to their causes. In the *Physikalische Zeitschrift* for February 15 there is a paper by Dr. L. Gabelli which remedies this omission. Breaks are classified as due either to external or to internal causes. The external causes may be localised, as in the case of a blow struck on the surface of the glass with a pointed or blunt object, or be distributed over the surface, as in the case of hydrostatic pressure. The author shows by means of numerous figures that in each case the break has characteristics which enable the cause to be assigned, and in the case of hollow vessels there is a difference between the effects due to the same cause applied within or without. Of breaks due to causes within the material, those which fall under unequal heating are most common, and, like the previous ones, have their own characteristics, which depend greatly on the distance of the heated point from the edge of the material. The author hopes that the technical importance of the subject will lead others to continue these investigations.

WE learn from a note in *Engineering* for March 18 that the Bureau Veritas International Register of Shipping will shortly issue a new edition of its rules. The new publication will be very comprehensive. No change has been made in the method of determining the scantling numerals, which remain as formerly, the basis being the sum of the breadth and depth, and the product of the length, breadth, and depth. For thickness of material, one-fiftieth of an inch has been adopted as a unit, instead of one-thirty-second as formerly. This will admit of ready comparison with the British standard decimal system on the one hand and with the metric system on the other.

MESSRS. WILLIAMS AND NORGATE will issue very shortly, in conjunction with Messrs. B. G. Teubner, of Leipzig, a volume compiled and edited by Yokshio Mikami, entitled "Mathematical Papers from the Far East."

MESSRS. WATTS AND CO. have issued for the Rationalist Press Association, Ltd., a cheap reprint of "The Nature and Origin of Living Matter," by Dr. H. Charlton Bastian, F.R.S. This edition has been revised and slightly

abbreviated, and its price in paper covers is 6d., or in cloth, with Dr. Bastian's portrait as frontispiece, 1s. net.

A CATALOGUE of rare and valuable books and autograph documents and letters has been issued by Mr. Bernard Quaritch, of Grafton Street, London, W. The catalogue runs to 336 pages, and contains full sections dealing with works on astronomy, mathematics and physics, topography, and other subjects likely to appeal to scientific readers.

A SEVENTH edition of "A Treatise on Ore and Stone Mining," by Sir Clement Le Neve Foster, F.R.S., has been published by Messrs. Charles Griffin and Co., Ltd. The work appeared first in 1894, when it was reviewed at length in NATURE (vol. 1, p. 543) by the late Mr. Bennett H. Brough, who was afterwards responsible for the sixth edition, issued in 1905, and reviewed in NATURE of January 4, 1906 (vol. lxxiii., p. 220). The present issue has been revised by Prof. S. Herbert Cox, who has adhered to the original general scheme of the book. The price of the treatise is 28s. net.

THE issue of the *British Journal of Photography* for March 18 is the third of the special "colonial" numbers, in which that journal addresses itself specially to photographers and photographic dealers abroad. The enlarged text pages contain contributions on studio matters, including the first of a series of articles for the young professional portraitist on securing different effects of lighting. Mr. Edgar Clifton writes on the care of lenses in the tropics, Mr. Welborne Piper on the adjustments of the enlarging lantern, whilst a large proportion of the letterpress deals with recent introductions by photographic manufacturers.

OUR ASTRONOMICAL COLUMN.

THE SOLAR ECLIPSE OF 1912 APRIL 17.—In an article published in the *Revue générale des Sciences* for February 15, M. D. Savitch discusses at full length the circumstances of the solar eclipse of 1912 April 17.

The central line passes through Portugal, the Bay of Biscay, and across France to Belgium, its direction being north-east. It passes within ten miles of Paris. Only about three times a century is an eclipse total in France.

The magnitude of the eclipse along its central line is continually diminishing, and the character of the eclipse changes from total to annular. The point, however, where this change takes place can hardly be assigned with certainty, for it is largely displaced by a small change in the adopted semi-diameter of the moon; the difference of 1.18" between the values used by the Nautical Almanac and the *Connaissance des Temps* is sufficient to displace it by some hundred miles from a position out at sea to the neighbourhood of Paris.

In any case, totality is too short for the eclipse to be of much value in the usual way. Nor is there much reason to expect better results than usual from observations to determine the moon's position. No eclipse since 1715 plays a prominent part in determining the position of the moon, and the eclipse of 1715 and its predecessors are important because they are ancient rather than because they were accurately observed in the modern sense of the word accurate.

M. Savitch's article is clear, and illustrated by an excellent map.

THE COMETS (1910a AND HALLEY'S).—A large number of observations of comet 1910a are published in No. 4392 of the *Astronomische Nachrichten*, including those made at Kodaikanal, Cambridge, Helwan, and Greenwich. Mr. Michie Smith reports a number of positions, several of which, it is interesting to note, are referred to positions of a sun-spot. On January 31 Mr. Evershed traced the tail to a distance of 27° from the head.

Herr Konkoly reports the presence of the three hydrocarbon bands, in the spectrum of the comet, on January 26, and states that the continuous spectrum was faint, whilst a fourth band was suspected.

Dr. Kobold has carried his ephemeris back to the beginning of November, and shows that, although the comet was probably brighter than the sixth magnitude as early as December 1, it was apparently so near the sun as to render its discovery improbable. The ephemeris published in No. 4393 of the *Astronomische Nachrichten* indicates that the comet may become observable again about the first week in April as a morning star, but it will be faint and difficult. A note in the *Observatory* for March emphasises the necessity for such observations being made, if possible, because of their value in determining more rigidly the exact form of the orbit.

Dr. F. J. Allen kindly sends us a beautiful drawing of the comet depicting its form as he saw it on January 30 from the Mendip Hills; the observations were recorded in our article of February 10 (NATURE, No. 2102, p. 441). He directs especial attention to the pronounced curve of the tail towards its extremity, the direction beyond α Pegasi, the uppermost star shown, being nearly horizontal, and states that the comet as here shown is, relatively to the stars, too bright, while the head is perhaps

Comet 1910a. From a drawing by Dr. F. J. Allen.

a little too large; but the form and extent of the tail are as he saw it.

Dr. Allen, referring to the passage of the earth through the tail of Halley's comet on May 18, suggests that a well organised attempt should be made to collect some of the cometary dust which may then enter our atmosphere. It will be remembered that Prof. Turner, in his recent Royal Institution lecture, suggested that some such attempt should be made, by "bottling" some large quantities of the atmosphere. It is obvious that to have any hope of success the "bottling" would have to be done on a very large scale and under the most favourable and rigid conditions. Dr. Allen suggests a large chamber, carefully prepared and situated in a position where the air is usually very free from contamination, through which immense quantities of the atmosphere could be drawn and filtered. The filtering should be carried on before, during, and after May 18, in order that differential tests might be applied to determine the extra-terrestrial origin of the collected dust. As the cometary dust, and gas, may take days, or weeks, to diffuse sufficiently to reach the earth's surface, the experiment should be continued for some time after the critical date, thus affording opportunity to detect any differences in the collected matter.

In No. 5 of the *Revue générale des Sciences* (March 15, p. 177) M. G. Renaudot makes the interesting suggestion that the periodicity of comets, or of Halley's comet especially, was known and recognised by the ancient Hebrews. He bases this suggestion on a passage in the Talmud, where one of two voyagers explains that he has laid in a stock of flour, rather than bread, because "There is a very bright star which appears every seventy years and which deceives navigators. Thinking that she may surprise us during this voyage, and so prolong our journey, I have provided the flour." M. Renaudot gives reasons why the expected object should be considered as a comet, rather than as a long-period variable, for instance, explains that 70 instead of 75 is in accordance with the habit of giving round numbers, and states that the existence of the two important personages between whom the dialogue took place is well attested historically.

A second edition of Prof. Turner's British Association address on "Halley's Comet" has just been issued by the Clarendon Press at the price of 1s. net.

EPHEMERIS FOR EROS, 1910.—To facilitate observations of Eros during the coming opposition, Prof. Wendell has computed an ephemeris, which is published in Circular No. 153 of the Harvard College Observatory. Unfortunately, the planet will not be observable in these latitudes, its declination at opposition (May 23) being $46^{\circ} 31' S.$, but, as its orbit and light-variations are so peculiar, it is hoped that a number of observations will be secured at southern observatories.

PROF. DOBERCK'S DOUBLE-STAR OBSERVATIONS.—In continuation of a list which appeared in Nos. 4327-8 of the *Astronomische Nachrichten*, Prof. W. Doberck now publishes his observations of a great number of doubles, at Sutton during 1909, in Nos. 4394-5 of the same journal. Each observation is recorded separately, and the position-angle and distance of each pair are given for the mean epoch of observation.

DANIEL'S COMET, 1909e.—A photograph of Daniel's comet (1909e) was secured by Dr. Wolf on February 28, when the comet's magnitude was 15.0. It now appears that this comet belongs to the Jupiter, and not to the Uranus, family of comets, as was at first suspected.

THE NATIONAL PHYSICAL LABORATORY IN 1909.

THE general board of the National Physical Laboratory held their annual meeting at the laboratory on Friday last, March 18, when the report of the work done during 1909 was presented, and the programme of work proposed for the year 1910 was approved. The chair was taken by Sir Archibald Geikie, as president of the Royal Society, and Lord Rayleigh, chairman of the executive committee, was also present. A large number of guests were invited to inspect the various departments of the laboratory.

Two new branches of the work claim attention this year. The first of these is the national experimental tank for experiments on ship models, which is being constructed at a cost of about 20,000l., provided by the generosity of Mr. A. F. Yarrow. A maintenance fund for carrying on the work of the tank for the first ten years has also been provided with the aid of the Institution of Naval Architects. With regard to the details of the working of the tank, assistance will be given, under a scheme printed in the laboratory report, by an advisory committee composed of members nominated by the Institution of Naval Architects and by the executive committee of the laboratory.

The tank itself, and the office buildings and workshops required, are now nearly completed. The length of the tank is 500 feet at the full depth of $12\frac{1}{2}$ feet, and the width 30 feet. At the north end are docks for receiving the models, while at the south end is a shallow "beach" for breaking the waves. As was shown by Dr. Glazebrook in a report presented in March, 1909, to the Institution of Naval Architects, models up to 20 feet in length and 3 feet in breadth can be tested in a tank of the width stated without any appreciable effect on the results due to the sides.

The models will be towed along by a carriage, electrically driven, spanning the tank and running on rails on either

side. This carriage carries the observers and dynamometers. The models will usually be made of paraffin wax, and the equipment will include special model-cutting machinery. None of this apparatus, however, is yet installed, and we hope, at a later date, to give a more detailed account of the tank and of the special apparatus employed.

The second large development of the work during 1909 is the formation of a division for research in aeronautics. This work has been undertaken in accordance with the announcement made by the Prime Minister in the House of Commons on May 5, 1909, and is under the general superintendence of the Advisory Committee for Aeronautics then appointed. Rapid progress has been made during the year with the provision of the necessary equipment for the experimental work at present planned. This includes an air channel 4 feet square in section by 20 feet long for general work in aerodynamics, a whirling table 60 feet in diameter for propeller testing, in a special building 80 feet square; dynamometers for motor testing, with arrangements for an air blast for air cooling; and two wind towers for work on a large scale in the open. All this apparatus has been erected, and experiments have been for some time in progress. The division is under the charge of Dr. Stanton as superintendent of the engineering department, and his great experience on the subject of wind pressure will be especially valuable. To provide the increased accommodation necessary, two more bays have been added to the engineering building.

The testing of balloon fabrics also constitutes an important branch of the work. Tensile and bursting tests have been carried out in the engineering department; while in the chemical department a special apparatus has been devised for the determination of the permeability to hydrogen. We may, perhaps, be able on another occasion to give further particulars of the aeronautical equipment.

Turning now to the physics department, in the electrical standards division good progress has been made with the erection of the Lorenz apparatus for the determination of the ohm in absolute measure, and this is now nearly complete. The coils, wound on marble cylinders, have been made in the laboratory; the main part of the machine, by the kindness of Sir Andrew Noble, has been constructed at Elswick. The determinations to be made with this will be the chief work in this division during the current year. With regard to standard cells, a research has been in progress to determine the limits of temperature between which cadmium amalgams of various concentration can be usefully employed, the results of which were communicated to the Physical Society by Mr. F. E. Smith in a recent paper. The general conclusion arrived at is that an amalgam containing $12\frac{1}{2}$ per cent. of cadmium cannot safely be used below $12^{\circ} C.$, and the substitution of a 10 per cent. amalgam is recommended. This can be relied upon to give constant results at a definite temperature for all temperatures between 0° and $51^{\circ} C.$

We have previously made reference to the new order in council lately issued relative to the electrical units, the outcome of the work of the International Conference in London in 1908. To complete the work of the conference, representatives from the chief standardising laboratories are to meet at Washington shortly to continue jointly the researches necessary to decide on a definite value for the E.M.F. of the Weston cell.

Another matter in which international cooperation is being arranged is the question of the methods of measuring hysteresis and eddy loss in steel sheet. A modification of the Epstein method has recently been devised by the Bureau of Standards which appears to give accurate results, and investigations relative to this question have been in progress at the laboratory.

In the electrotechnics division much attention has been given to perfecting the equipment for alternating-current measurements. Features of special interest are the non-inductive water-cooled tube resistances, described in a paper communicated to the Institution of Electrical Engineers, and the quadrant electrometer for use as an alternating-current wattmeter. The 100,000-volt transformer equipment has been completed, and has been employed in an investigation into the properties of different varieties of ebonite, while a research on insulating materials is in progress. In the photometry section a considerable

amount of work has been done towards setting up standards for use in measurements of metallic filament lamps. The determination of the candle-power of these in terms of the pentane standard involves a comparison between lights of different colour, and in the process of stepping up as many observers as possible must be employed to obtain a representative mean.

Early in the past year an agreement was arrived at between the authorities in America, France, and this country as to a common light unit, the American unit being altered by 1.6 per cent. to bring it into agreement with the British unit expressed in terms of the 10-candle Harcourt pentane lamp.

In the thermometry division the work has consisted in great measure of improvements in the equipment, especially with the view of the extension of the work on the fundamental gas scale to higher temperatures. It is hoped that a useful material for gas-tight vessels has been obtained, but further progress required power for heating larger furnaces, which has now been provided.

In the metrology division an interesting experiment is being tried in the use of silica as a material for standards of length. The advantages are a low coefficient of expansion and small thermal hysteresis, *i.e.* the temporary change in length due to a cycle of temperature change is small. A standard has been constructed with flat and parallel end slabs fused into a hollow cylindrical rod, the slabs being platinised to receive the divisions. The study of this standard will be continued during the present year.

Important additions have been made to the sets of standard screw gauges in the possession of the laboratory. These now comprise complete series of British standard Whitworth threads, British standard fine threads, British standard electrical conduit gauges, and B.A. threads. They have been constructed by Armstrong, Whitworth and Co. to the dimensions laid down by the Engineering Standards Committee. Two large machines for pitch and diameter measurements are also being constructed at Openshaw.

The 50-metre mural base for verification of surveying tapes has been completed. The length of this base is stepped out against a 4-metre standard bar, itself determined against the standard metre. Another important piece of work has been the re-erection of the Blythwood ruling machine for ruling diffraction gratings. By shifting the periodic error connecting cam from one end of the screw to the other, the length of grating which can be ruled has been increased from 5 to 8 inches. The exact setting of the periodic error cam alone remains to be done to enable the ruling of gratings to be commenced.

A useful piece of work in the optics division has been the devising of a new apparatus for testing photographic shutters. The method is essentially that of Sir Wm. Abney, with the use of a vibration galvanometer in place of a siren as a time recorder.

In the engineering department a large number of researches are in progress. Dr. Stanton is continuing his wind-pressure work, as well as the research on the resistance of materials to alternating stresses of high frequency. Some very interesting results have been obtained with regard to the heat transmission and friction of air currents in pipes, and a paper on the resistance of plates and models in a uniform current of water was communicated to the Institution of Naval Architects. The water channel used for these experiments has been utilised also for work in connection with aeronautics, and gives results closely comparable with those obtained in an air channel, allowance, of course, being made for the difference in density. A valuable paper by Mr. Bairstow on the elastic limits of material under alternating stress has been published in the *Philosophical Transactions*, and contains interesting experimental conclusions relative to the theory of fatigue. Another research of importance which is in progress relates to the strength and efficiency of welded joints, from which the preliminary conclusions have been reached that the material at a welded joint is often in a dangerously brittle state, and that a long weld is essential to secure even moderately good results.

In the department of metallurgy and metallurgical chemistry, the work done for the Alloys Research Committee of the Institution of Mechanical Engineers was

embodied in the ninth report, on some alloys of copper, aluminium, and manganese, presented to the institution early in 1909. Further work on the light alloys of aluminium is in progress. The eutectics research, on which a first communication appeared in 1908 in the *Philosophical Transactions*, has been continued, attention being especially directed to the mode of solidification of eutectic alloys. A preliminary account of an investigation into the effects of strain at high temperatures, recently published in the *Proceedings of the Royal Society*, presents features of interest. It was established that deformation by intra-crystalline slip occurs at temperatures up to 1100° C., while the three allotropic modifications of iron known as α , β , and γ iron showed marked differences in the effects of strain. A number of cases of failure in practice have been investigated, and in connection with these a systematic study is being made of the modes of fracture of steel.

The work of the observatory departments of the laboratory, at Kew and Eskdalemuir, is of a distinct character, and need not be referred to now in detail. Mention must, however, be made of the admirable piece of work completed by Dr. Chree, in the discussion of the magnetic curves of the National Antarctic Expedition of 1902-4, printed in the volume of "Magnetic Observations" issued by the Royal Society early last year.

INSTITUTION OF NAVAL ARCHITECTS.

THE spring meetings of the Institution of Naval Architects commenced on Wednesday, March 16, in the rooms of the Royal Society of Arts. The institution has now completed its first fifty years of existence, and proposes to celebrate its jubilee by special meetings commencing on July 4. The council also recommended that the present time is favourable for applying for incorporation under a Royal charter, an opinion which was endorsed by the members at the Thursday meeting. A presidential address was delivered by Earl Cawdor, and premiums were awarded to Dr. T. E. Stanton and Mr. H. C. Anstey for papers, respectively, on the resistance of thin plates and models in a current of water, and on the application of internal-combustion engines for marine propulsion. Thirteen papers in all were presented at the meetings, abstracts from some of which we give below.

A systematic series of experiments on wake and thrust deduction has been carried out recently at the experimental tank of Messrs. John Brown and Company's establishment at Clydebank, and form the subject of a paper contributed by Mr. W. J. Luke. Experiments were made with twin and with single screws, and in all cases where twin screws were run the experiments were made in both directions of rotation. The work involved the carrying out of at least 2000 experiments. The effective horse-power may be expressed as the product of the thrust horse-power and the hull efficiency, the latter quantity being the product $(1+w)(1-t)$, where w is the wake fraction and t is the fraction of the total thrust by which the tow-rope resistance is less than the thrust exerted by the screw when propelling the ship. The experiments were directed towards determining the variations in w and t when (a) speed, (b) diameter, and (c) pitch ratio were varied. With naked models a decrease in wake fraction is evident with an increase of speed; changes which appeared for variations in diameter might be as much owing to alterations in clearance; variation in pitch had little or no effect on either of the hull-efficiency elements.

Prof. B. Hopkinson, in his paper on the measurement of shaft horse-power by torsion-meters, directed attention to the need for further experimental work on full-sized shafts with the view of ascertaining whether twist may be produced by means of a longitudinal push or pull. Such would imply, if no torque be applied, a peculiar structure of the shaft, which might be described as a helical arrangement of the fibres. Mr. C. E. Stromeyer gave results of his observations of the brittleness of mild steel due to nitrogen. It has not yet been possible to combine nitrogen with steel by merely heating the two together, but this may be effected by heating steel in an atmosphere of ammonia. Ammonia may be present in blast furnaces if

the coking of the fuel has not entirely removed the nitrogen which was present in the coal. It also seems that, when nitrogen has once entered pig-iron in the blast-furnace, it cannot be removed by subsequent heating. It seems desirable to ascertain more definitely by further experiments how titanium acts in practice in the removal of nitrogen from steel.

A very important paper was presented by the Hon. C. A. Parsons on the application of the marine steam turbine and mechanical gearing to merchant ships. The steam turbine has not hitherto been applied to vessels of slow normal speed on account of the high initial cost and inferior economy in steam. No promising scheme has, as yet, been evolved whereby the efficient speed of the turbine may be reduced and that of the propeller increased for vessels of 12 knots sea speed and under. The only approach of meeting these conditions has been in the combination system of reciprocating engines and turbines, in which the lower stages of the expansion are effected in the turbines.

Provided the losses in transmission, first cost, and cost of maintenance are not too great, the most satisfactory solution for slow-speed vessels would appear to be by means of gearing. Mechanical, electrical, and hydraulic gearing have been proposed or applied, and the author proceeded to give an account of his successful experiments in developing a mechanical gearing.

Helical and double helical gear wheels of fine pitch were probably first introduced by De Laval in connection with his turbine, and have proved to be very satisfactory and efficient. Mr. Parsons has had several sets made. One of these, made in 1897, gearing from 9600 revolutions of the turbine to 4800 of the dynamo, transmitted 300 horsepower with an efficiency of more than 98 per cent. This gear ran fourteen hours a day for about a year. Recent and better cut gears have given a total loss in the gear-case of 1.5 per cent., including friction of gear and bearings.

The author was thus led to experiment with a view to obtain comparative figures for a cargo vessel, first fitted with ordinary reciprocating engines, and then with turbines and mechanical gearing of the above-mentioned type. The *Vespasian* was purchased for this purpose. Her dimensions are:—length on load water-line, 275 feet; breadth moulded, 38 feet 9 inches; depth moulded, 21 feet 2 inches; mean loaded draught, 19 feet 8 inches; displacement, 4350 tons. The vessel was first fitted with triple-expansion surface-condensing engines of ordinary pattern, cylinders 22½ inches by 35 inches by 59 inches, and 42-inch stroke. There were two boilers, each 13 feet in diameter and 10 feet 6 inches long, of total heating surface 3430 square feet, and grate area of 98 square feet. The working pressure was 150 lb. per square inch. A four-bladed cast-iron propeller was fitted, having a diameter of 14 feet, pitch 16.35 feet, and expanded area of 70 square feet.

Before proceeding on the experimental voyage from the Tyne to Malta, the reciprocating propelling machinery was completely dismantled and overhauled. The machinery was thus brought into an efficient and first-class working order. Suitable tanks were provided for measuring the steam consumption. Loaded with a cargo of coal, the *Vespasian* left the Tyne on June 26, 1909, and careful measurements of coal and water consumption were made throughout the voyage by a special recording staff.

On the completion of this voyage the vessel returned to the turbine works, the reciprocating engines were removed, and turbines and gearing fitted. The importance of these trials lies in the fact that the only alteration made in the vessel was in the type of propelling engines. Boilers, propeller, shafting, and thrust blocks remained the same as for the reciprocating engine.

The turbine machinery consisted of two turbines in series, one high-pressure and one low-pressure, the high-pressure turbine being on the starboard side of the vessel and the low-pressure on the port side. At the after end of each turbine a driving pinion is connected, having a flexible coupling between the pinion shaft and the turbine, the pinion on each side of the vessel being geared into a wheel which is coupled to the propeller shaft. A reversing turbine is incorporated in the exhaust casing of the low-pressure turbine. The usual air, circulating, feed, and bilge pumps are driven from the forward end of the gear-wheel shaft. The turbine and pinion shaft bearings are

under forced lubrication; the teeth of the gear wheels are lubricated by means of a spray pipe extending over the whole width of the wheel face.

The high-pressure turbine is 3 feet maximum diameter by 13 feet over-all length, and the low-pressure 3 feet 10 inches in diameter by 12 feet 6 inches in length. The turbines were balanced for steam thrust only, the propeller thrust being taken up by a thrust block. A new condenser with a vacuum augmentor was fitted. The gear wheel is cast iron with two forged steel rims shrunk on. This wheel is 8 feet 3¼ inches in diameter of pitch circle, and has 398 double helical teeth of circular pitch 0.7854 inch. The total width of face of wheel is 24 inches; the teeth have an inclination of 20° to the axis. The pinion shafts are of chrome nickel steel, 5 inches diameter of pitch circle, with twenty teeth of 0.7854 circular pitch. The ratio of the gear is 19.9 to 1.

On completion of the alterations, at the end of February of this year, the vessel was loaded to the same draught and displacement as that recorded for progressive trials on the Hartley mile with reciprocating engines. In the short interval since the completion of the alterations the vessel has been out to sea on four occasions.

Mr. Parsons gives full information and curves showing the results of the trials. We abstract the following important figures from these.

Water Consumption per Hour, for all Purposes.

Revolutions of propeller	Speed of vessel, knots	Lbs. of water per hour		Savings, per cent.
		Reciprocating engines	Turbines	
60 ...	8.87 ...	11,750 ...	10,750 ...	8.5
65 ...	9.55 ...	14,500 ...	12,600 ...	13
70 ...	10.2 ...	17,500 ...	14,750 ...	16

The turbines and gearing have given no trouble, and have worked satisfactorily, with very little noise or vibration, throughout the trials. There is no appreciable wear on the teeth or bearings. It is proposed to put the vessel into commission and run extended trials. Mr. Parsons further added that the saving in weight on installing the turbines amounted to 25 per cent.

Speakers in the discussion were unanimous in commending Mr. Parsons for his success, which is likely to revolutionise the means of propulsion of tramp steamers, which, as Sir William White remarked, form the backbone of mercantile business. Prof. Ewing pointed out the greater simplicity of mechanical gear as compared with electrical, and also directed attention to its much higher efficiency. He thought it most appropriate that the solution of this important problem should have fallen to the lot of the inventor of the steam turbine. The economy of Mr. Parsons's new system could be simply expressed as the saving of one boiler in six required for ordinary reciprocating engines.

AN INSTRUCTIVE EARTH MODEL.

AT the Hotel Cecil on March 17 Mr. G. R. Gill showed a large model of the earth which, while large enough to admit of the representation of surface features in detail, can be packed into a comparatively small cabinet. A rectangular box 5 feet by 3 feet by 1½ feet is wheeled easily into position, the folding lid is opened, a quadripod arrangement is raised and made rigid, a steel axis with aluminium ends is slipped into position, eighteen meridians are fitted into the ends and stay in place by their own elasticity, the three parts which go to form the equator are placed by the side of the box, and this gives the arrangement of the skeleton globe which is shown in Fig. 1.

The slope of the axis is adjustable to any angle, that of 23½° being noted by a bell signal. The globe can be made to rotate by hand or by electric motor. The diameter of the globe is 4 feet 2½ inches, which gives a scale of 1/10°. The meridians are made of twelve thicknesses of very thin wood cemented and rivetted together.

The equator is then fixed, and from a cupboard thirty-six sections are taken and fitted into place. Fig. 2 shows the operation of inserting the last section, and shows, approximately, the height of the erected globe. The sections are of mild steel faced with *papier-mâché*, and are

sufficiently strong to resist fairly rough treatment. The surface shown in Fig. 2 is that of the earth in relief, where the scale is $1/5 \cdot 10^3$, giving an exaggeration of twenty times. This surface shows the relief of the land, the depressions of lakes and rivers, while the limits of pack- and drift-ice in the Polar regions are ingeniously marked. From the scientific point of view it is perhaps a pity that the relief of the ocean beds has not been shown, as one of the important advantages of a globe on this scale appears to be the possibility of an adequate realisation of the gradients of the land surface, and such a conception loses more than half its value when it is limited to the subaerial parts; possibly the inventor, Mr. G. R. Gill, will be able to make sections to show the complete relief of the solid crust.

Other surface sections are available; first, political sections showing by divers colours the great world empires, the railways, the rivers, and the ocean and cable routes;

FIG. 1.—Meridians in place.

secondly, plain sections on which the demonstrator may draw his own sketches. These sections are interchangeable, so that pupils may be tested as to their power to draw coast lines, &c. The whole globe can be set up in a few minutes, and a few seconds suffice for the changing of sections. Additional attachments are provided so that the large globe may be used to represent the sun, and a set of small balls, mounted at varying slopes, the planets; the Pole Star and Ursa Major are represented by a set of small balls to be fixed to the axis. There appears to be no difficulty in arranging the surface sections so that the upper half represents the southern hemisphere.

For purposes of measurement, and for the elucidation of "great circle sailing," schoolmasters will probably ask Mr. Gill to supply a thin steel band, graduated in degrees, which could be used to demonstrate and measure the shortest distance between two places upon the earth.

The model is sufficiently large and rigid that a youth may climb into and hide within the interior, and it is probable that for teaching purposes the possession of this globe would render the use of wall maps of the continents unnecessary for class work in geography. The teacher of geography by the methods of modern science will find this globe extremely useful, not only as his final resort in summarising the pupils' studies of a definite region, but in putting that region in precise relationship with the

neighbouring regions; in our opinion there seems to be no end to the many practical exercises of a "heuristic" nature which pupils could be set, even to the extent of several at a time working on the one globe.

Many little devices suggest themselves at once whereby the main factors of the earth's climatic conditions might become more real; it will suffice to suggest one use of a slightly different nature; the room is darkened, the rays from the lantern are centred accurately on the model, questions of local time and sun time are discussed, and with a needle to represent a stick the shadow exercises so common in school work in the playground are repeated on the globe, with this advantage, that the graph obtained to show the sun's altitude, which took the whole of one school year to make, may now be made in a shorter period, when the work may be carried through without a break. The inventor may be congratulated on the way in which he has surmounted many mechanical difficulties, and in

FIG. 2.—Inserting the last section.

which he has produced an important addition to the apparatus which may be used to teach geography scientifically.

B. C. W.

THE CARNEGIE FOUNDATION FOR THE ADVANCEMENT OF TEACHING.

THE fourth annual report of the president and treasurer of the Carnegie Foundation for the Advancement of Teaching is now available, and deals with the work of the year ending September 30, 1909. It will be remembered that, in dealing with the third report in our issue of June 3, 1909 (vol. lxxx., p. 399), Prof. J. Edgar described at length the scope and character of the foundation, and it is necessary here to deal only with points of interest in the work of the past year.

During the year the foundation granted 115 pensions amounting to 35,400*l.* It is now paying 318 pensions, the cost being 93,200*l.* The professors receiving these pensions are from 139 colleges, distributed over forty-three States of the Union and provinces of Canada. To the accepted list of colleges, that is, to the list the professors of which may regularly receive pensions under fixed rules as a right and not as a favour, seven colleges were admitted during the year. The governors and legislatures of twenty-six

other States asked that their universities should also be admitted to the foundation. The fact that only five State institutions, one of these in Canada, have been admitted to the Carnegie Foundation, after a year of administration of the rules under which tax-supported colleges and universities became eligible, testifies to the scrutiny exercised in the admission of institutions. There are now sixty-seven institutions on the accepted list.

The second section of the report is devoted to an examination of the working of the rules for retirement, as shown in the experience of the past four years. As a result of the experience, two changes were made in the rules by the trustees; one extends the benefits of the retiring allowance system so that service as an instructor shall count toward the earning of a retiring allowance. Heretofore only service in the rank of professor was counted toward an allowance. The other change makes retirement after twenty-five years of service possible only in the case of disability unfitting the teacher for active service. Except in the case of such disability, the teacher can, under the rules as now framed, claim a retiring allowance only upon attaining the age of sixty-five. Formerly a professor might retire after twenty-five years of service. This change in the rules does not, however, deprive the widow of a teacher who has had twenty-five years of service of her pension.

The third section of the report is devoted to tax-supported institutions. Agricultural education and the agricultural college are also treated at length. The trustees make clear their intention to ask of the institutions of every State whether the university and the college of agriculture are competing or cooperating parts of a State system of education. The low standards and general demoralisation resulting from the competition of these two types of tax-supported institutions in the various States are pointed out. In the fourth section of the report it is said to be noteworthy that only a small proportion of the colleges and universities calling on the public for support print a straightforward financial statement showing what they do with the money collected from the public. Following the report of the president is the report of the treasurer. In this matter the foundation has followed the advice which it gives to other institutions, and prints a detailed statement, showing, not only the larger items of expense, but even the individual salaries which are paid.

BOSTON MEETING OF THE AMERICAN ASSOCIATION.

EXTRACTS FROM THE ADDRESSES OF SECTIONAL PRESIDENTS.

The Teaching of Physics.

IN his address to Section B (Physics), Prof. K. E. Guthe discussed reforms needed in the teaching of physics. He maintained that the decision as to how physics should be taught rests finally with those men who know the subject, understand the spirit of the science, and for this reason are the only judges of its characteristic educational value. Concerning himself particularly with the teaching of physics in American colleges and universities, he proposed two questions, "May not the preparation which professors give future teachers be faulty?" and "May not the professors' teaching be capable of improvement?" He said he believed both these questions should be answered in the affirmative. The system of the teaching of physics in many American colleges and universities, he maintained, more adapted to train professional physicists than future high-school teachers. The two would receive a different training. The ideal high-school teacher is one who has passed through a complete and thorough graduate course. At the present time the great majority of American high-school teachers do not go beyond graduation, and Prof. Guthe would deplore any attempt to crowd so much physics into the undergraduate course as the physicist finally turned out lacks the general culture which an undergraduate course should give. American professors of physics should, he insisted, emphasise more problem work in connection with the elementary course. An utter helplessness of many higher students in attacking elementary problems is not unusual. The laboratory work given with the elementary course is

frequently quite insufficient, and a somewhat advanced course, not in special lines, but covering the whole field, will do an untold amount of good. Finally, there should be a general review of the whole subject from a higher point of view than is possible in the elementary course. The calculus might be a required study for this. At this point subjects might be taken up which have been omitted in the first course; the treatment could be more thorough and more exact. The introduction of such an advanced course would also have a good influence upon the first course. Prof. Guthe advised future teachers of physics to take also a course in meteorology, a short course in dynamo-electric machinery, and an elementary course in instrument-making, all of which might properly be given in the physics department. Such a graded course will produce, he thinks, teachers to whom may be left without hesitancy the question as to how physics should be taught in the high school. The second proposition considered was, "Professors of physics are far from being unanimous in the use of certain terms, and frequently employ the same term to designate two entirely different physical quantities." This means that enough attention is not paid to the very things which make physics so valuable as a training of the mind, namely, clearness of thinking and accuracy of expression. Prof. Guthe cited and considered numerous cases in point, among them being the terms used in connection with pressure, surface tension, measurement of quantities of heat, and fields of magnetic force.

The Study of Solutions.

Prof. Louis Kahlenberg, of the University of Wisconsin, presided over Section C (Chemistry), and in his address dealt with the past and future of the study of solutions.

The study of solutions, he said, was begun with the chemical conception of solutions, and upon this conception many relationships were worked out during the first eighty-seven years of the nineteenth century. The older chemists clearly recognised that whether solution will take place or not in a given case is first of all determined by the chemical nature of the substances brought into contact with each other. They saw that the temperature factor was next in importance, and that pressure was of vital consequence when a gas was under consideration, but of slight importance in the case of solids and liquids. When the conception that solutions are mere physical mixtures came to the foreground, through the introduction of gas analogies and the intense propagandism of the dilute school, the fact that the act of solution is really chemical in character was lost sight of by many able, enthusiastic young investigators. In the ardour of their quest they were misled, and unwittingly they naturally misled others. It is really pitiable to see how physiologists, having thus taken up these misconceptions of the nature of solutions, are still wasting precious time in endeavouring to work out the complicated and very important processes that occur in living plants and animals. In these problems, which are in reality perhaps the very greatest that confront us at the present day, theories of solutions based on gas analogies are of no avail. They are thoroughly misleading, and worse than worthless here.

The clear recognition that solutions are really chemical in character, and that there is no wide gulf that separates the act of solution from other chemical phenomena, will do much toward furthering the future study of the subject. Years of experimental study of the chemical, physical, and physiological properties of a long list of both aqueous and non-aqueous solutions have led to the conviction that the act of solution is chemical, that solutions are chemical combinations, and that we can only make real progress toward a better understanding of the various solutions by recognising this as the basis of all our future work. The efforts to gain a better insight into the different solutions that confront us must be chiefly experimental, rather than mathematical; for in the study of solutions, just as in the study of chemical compounds in the narrower sense of the word, we are continually confronted with discontinuities. Now discontinuous functions cannot be handled mathematically at present, not even by the greatest of our mathematicians, for though work of this kind has been begun, it is still in a very rudimentary stage. It is highly probable, too, that the renewed study of solutions

from the chemical point of view will greatly aid us in getting a broader and more correct conception of the nature of chemical action itself. Certainly in living beings we have numerous, fundamental, and deep-seated chemical changes going on continually with apparently the greatest ease at ordinary temperatures and pressures, and it is tantalising that we are unable to comprehend how this is all brought about. In the unravelling of the questions that here confront us a clear recognition that solutions are chemical in nature will be of the greatest service.

Engineering as a Profession.

Prof. G. F. Swain, of Harvard University, addressed Section D (Mechanical Science and Engineering) on engineering as a profession. During the course of his remarks he said:—

The field of engineering is more extensive than that of any of the three so-called learned professions, and the different branches of the profession differ from each other to such an extent as in some cases to have little in common, except a knowledge of the general principles of physics, chemistry, mechanics, and other sciences. The profession of the physician, it is true, is divided into many specialities, but while the throat specialist deals with the throat, and the stomach specialist with the stomach, they are all dealing with the human body, in which all the parts and functions are closely interconnected; but even within the field of what is termed civil engineering, the railroad engineer and the irrigation engineer, or the railroad engineer and the architectural engineer, have little in common.

The work of the engineer as applied to any contemplated project consists essentially of four parts, first, to ascertain whether anything should be done, and, if so, what should be done; second, to design and formulate the means to be employed in doing it; third, to select the proper materials; and, fourth, to carry on the actual work into execution. As the engineer's problem is to adapt the materials, the forces, the sources of power in nature to the use and convenience of man, it is clear that in order to fulfil his calling to the highest extent the engineer should be scientifically trained—that he should be familiar with the fundamental principles which govern natural phenomena. Different branches of science are required in varying degrees in the different branches of the profession, but every engineer should know, and know thoroughly, the fundamental principles of chemistry, physics, mathematics, and mechanics. The engineer should be possessed of the true scientific spirit, loving the study of science for its own sake as well as for its applications, and trained to seek always the truth, the whole truth, and nothing but the truth; but the work of the engineer deals, not with science for its own sake, but with its applications to the practical affairs of men. The engineer must, therefore, be above all a *practical man*. He must not be a pure theorist, a dreamer, a visionary. He must see in his mathematical formulae a meaning, and not a simple accumulation of letters. The engineer, then, must not only be a scientific man, but he must be, first and foremost, a practical man; and, on the whole, the latter is more important than the former, although it is in the proper combination of the two that the greatest excellence will result.

The engineer, unlike the true man of science or mathematician, does not work in his laboratory or his study—his work is with the affairs of men. Engineering is more than half business, and the successful engineer, therefore, must be to a considerable extent a *business man* and a *financier*.

The profession of the engineer is a wide and varied one, but it requires varied qualifications, and demands pre-eminently an all-round man. It must not be forgotten, however, that without the scientific training, or at least the scientific spirit, the engineer will not attain the highest success. It is also evident that the thoroughly trained and capable engineer will find many opportunities to make himself useful in scientific as well as in administrative positions. He will also find many opportunities for doing general public service to the State or nation. Different men have different ideals of success, but the highest ideal is the one which most involves the idea of public service.

The Principles of Palaeogeography.

In his presidential address to Section E (Geology and Geography), Prof. Bailey Willis, of the University of Chicago, discussed the principles of palaeogeography. To summarise his remarks, it may be said that the following were given as the fundamental principles of the science:—

Ocean basins are permanent hollows of the earth's surface, and have occupied their present sites since an early date in the development of geographical features. This principle does not exclude notable changes in the positions of their margins, which have encroached upon continental areas.

Superficial oceanic circulation within the permanent oceans has persisted since an early stage of their existence, essentially in the great drifts which it now follows under the trade winds. It is probable that the present deep circulation of oceanic waters, poleward at the surface and equatorward below the surface, is due to exceptional refrigeration at the pole.

Diastrophism has been periodic. Viewed according to the periodicity of diastrophism, the earth's history falls into cycles, and each cycle into two periods, one of inactivity and another of activity. The periods of inactivity have been long, and during a major part of the duration of any such period the condition of inactivity has been common to the entire surface of the globe. The periods of diastrophic activity have been relatively short, and, as regards the whole surface of the earth in general, not contemporaneous. The great ocean basins are distinct dynamic provinces, and each has experienced periods of diastrophic activity peculiar to its individual history. The epochs of organic deformation are relatively brief. Folding and unconformity are frequently not contemporaneous even in one and the same dynamic province.

The processes of erosion, sedimentation, chemical activity, and organic evolution have been periodically conditioned according to the periodicity of diastrophism. The corresponding physical phenomena exhibit rhythmic changes which repeat similar conditions in like associations.

Erosion has been constant on land surfaces through the activity of some of the subprocesses, decay, denudation, or aggradation, which have never failed to make a record.

Marine sedimentation has sometimes been inconstant. During periods of diastrophic activity, when lands have been high, epicontinental seas small, and marine currents largely confined within deep ocean basins, sedimentation has been dominant; but during periods of diastrophic inactivity, when lands have been low, epicontinental seas extensive, and marine currents active on shallows and straits, sedimentation has failed in consequence of non-deposition or marine scour in appropriate situations.

The criteria of correlation are both physical and organic. The physical facts are basal. The organic forms, though endowed with evolutionary energy, are dependent and sequential.

Evolution of Intelligence.

Prof. C. Judson Herrick in his presidential address to Section F (Zoology) discussed the evolution of intelligence and its organs. In the course of his address he observed:—

Many a boy's brains are curdled and squeezed into traditional artificial moulds before he leaves school. His education is complete, and senile sclerosis of the mind has begun by the time he has learned his trade. For how many such disasters our brick-yard methods in the public schools are responsible is a question of lively interest. We who seek to enter into the kingdom of knowledge and to continue to advance therein must not only become as little children, but we must learn to *continue so*. The problem of scientific pedagogy is essentially this—to prolong the plasticity of childhood, or otherwise expressed, to reduce the interval between the first childhood and the second childhood to as small dimensions as possible. The docile or educational period of a mammal is largely devoted to the progressive mechanisation of the in-born plastic tissue of the higher correlation centres, i.e. to habit formation, or otherwise expressed, to the elaboration of acquired automatisms and reflexes of the type commonly referred to as lapsed intelligence. Much confusion has arisen from the failure to distinguish these individually acquired automatisms from those performed in the hereditary pattern i.e. lapsed intelligence from true instinct.

Summarising the argument of his address, Prof. Herrick said:—In our analysis of the behaviour of animals and its mechanisms we start with the tropism and the reflex. This type of response is in some of its simpler phases indistinguishable from the reactions of dead machines to the forces which actuate them; but the more complex reflexes, on the other hand, grade over into those behaviour types which we call intelligent. No one has yet succeeded in formulating a clear-cut definition of the limits of the reflex at either its lower or its higher extreme, and perhaps no one ever will, for the whole list of behaviour types from machines to men probably forms a closely graded series.

Even the simpler reflexes exhibit a measurable refractory phase or pause in the centre where the afferent impulse is made over into the efferent. When reflexes are compounded, there is another factor which may tend to modify or delay the response. This is the dilemma which arises when two or more reflex centres are so related that a given afferent impulse coming to one of them may take any one of several final common paths to the organs of response. The reflex response which actually emerges in such a case will generally be the adaptive one, i.e. the one which is best for the organism. The selection of the adaptive response in such a case may be termed *physiological choice*, and it always involves a lengthening of the refractory phase. In the neural tensions of the refractory phase of physiological choice we find the germs of the complex anticipatory reactions which in turn have nurtured the awakening intelligence.

The comparative study of animal behaviour in the broadest sense of the term is as essential as other branches of physiology to the comprehension of animal structures, and the enlargement of our knowledge of scientific fact in this field will contribute greatly to the more perfect integration of the three great branches of biology—*anatomy, physiology, and psychology*—and the correlation of the whole with other departments of knowledge. Our philosophy of nature is sound just in proportion as we succeed in effecting these correlations of experience.

Response to Chemical Stimulation.

In Section G (Botany) the president, Prof. H. M. Richards, of Columbia University, New York, addressed the members on the nature of response to chemical stimulation. Few, if any, physiologists would, he said, to-day be inclined to deny the ultimate chemical nature of the response of protoplasm to any form of stimulus. It is the purpose here to limit the examination of chemical irritation more especially to actual concrete chemical substances brought into relation with living protoplasm, and to inquire somewhat more particularly into their mode of action and the nature of the changes which they induce. The importance and fundamental nature of these reactions cannot be doubted. For this purpose we may include in the list all those substances which it may reasonably be believed induce, by their chemical action, constitutional changes in protoplasm. These substances may be mineral salts, organic compounds of great diversity of structure, including anaesthetics, which have been, perhaps, wrongly placed in a special class, and even gases of a simple constitution. They may be crystalloid, electrolytes or non-electrolytes, or perhaps even colloidal.

There are some points in regard to the normal food supply which have a direct bearing upon the question of chemical stimulation, as defined even in its restricted sense. In the case of some of the necessary food materials the concentration may vary within relatively wide limits before the effects of a lack or excess of these substances are observable. In such cases the increase necessary to produce a reaction may readily be so great as to involve a material increment in the isotonic coefficient of the solution, and thus confuse any result produced by any direct chemical stimulus with those initiated by the change in osmotic pressure. It is known, however, that some of the necessary salts which are required by the plant in relatively small quantities may, if the concentration be raised above the normal point, cause a secondary stimulation of growth, and eventually, if the increase be continued, become inhibitory after the manner of poisons.

In its restricted sense, chemical stimulation may be said to deal with the effects of chemical agents which are not only not necessary, but which may be positively deleterious

to the organism—poisons, in short. It has been established that many, if not all, classes of substances which exert a toxic action on protoplasm will become stimulatory if presented to the cells in sufficiently small doses. Somewhere between an infinitesimally weak solution which produces no reaction to the toxic dose which kills there is a stimulative optimum which gives the maximum of reaction. The question is not the possible ultimate lethal effect of these poisons, but how far they may serve to excite the protoplasm to extraordinary activity. The amount required to effect the latter result will naturally vary with the substance, certain mild poisons possibly never affecting the plant beyond the stage of stimulating growth, no matter how high a concentration was employed.

Prof. Richards concluded by dealing in some detail with the influence of chemical stimulus on the physiological activities of the plant, and why and in what manner the specific irritants used affect the quantitative, and even perhaps the qualitative, formation of enzymes.

Racial Differences in Mental Traits.

In Section H (Anthropology and Psychology) Prof. R. S. Woodworth, of Columbia University, the president of the section, in his address took up the question of racial differences in mental traits.

Our inveterate love for types and sharp distinctions, he said, is apt to stay with us even after we have become scientific, and vitiate our use of statistics to such an extent that the average becomes a stumbling-block rather than an aid to knowledge. We desire, for example, to compare the brain weights of whites and of negroes. We weigh the brains of a sufficient number of each race—or let us, at least, assume the number to be sufficient. When our measurements are all obtained and spread before us, they convey to the unaided eye no clear idea of a racial difference, so much do they overlap. If they should become jumbled together, we should never be able to separate the negroes from the whites by aid of brain weight; but now we cast up the average of each group and find them to differ, and though the difference is small, we straightway seize on it as the important result, and announce that the negro has a smaller brain than the white. We go a step further, and class the white as a large-brained race, the negro as a small-brained. Such transforming of differences of degree into differences of kind, and making antitheses between overlapping groups, partakes not a little of the ludicrous.

We seem to be confronted by a dilemma; for the group, as a whole, is too unwieldy to grasp, while the average, though convenient, is treacherous. What we should like is some picture or measure of the *distribution* of a given trait throughout the members of a group; and, fortunately, such measures and pictures can be had. Convenient and compact measures of variability are afforded by the science of statistics, and are of no less importance than the average; but still better, because closer to the actual facts, are graphic or tabular pictures of the distribution of the trait, showing the frequency with which it occurs in each degree. The distribution of a trait is for some purposes more important than the average.

After considering certain precautions and criticisms, Prof. Woodworth dealt in order with the various senses. The point of special interest is, he pointed out, as to whether the statements of many travellers, ascribing to the "savage" extraordinary powers of vision, hearing, and smell, can be substantiated by exact tests. The common opinion, based on such reports, is, or has been, that savages are gifted with sensory powers quite beyond anything of which the European is capable, though Spencer explains that this is a cause of inferiority rather than the reverse, because the savage is thus led to rely wholly on his keen senses, and to devote his whole attention to sense impressions, to the neglect and atrophy of his intellectual powers.

Sight, hearing, smell, touch, the pain sense were each considered in detail, and Prof. Woodworth came to the conclusion that, on the whole, the keenness of the senses seems to be about on a par in the various races of mankind. Differences exist among the members of any race, and it is not improbable that differences exist between the averages of certain groups, especially when these are small, isolated, and much inbred. Some interest, said

Prof. Woodworth later, attaches to tests of the speed of simple mental and motor performances, since, though the mental process is very simple, some indication may be afforded of the speed of brain action. The reaction time test has been measured on representatives of a few races, with the general result that the time consumed is about the same in widely different groups.

Chemical Regulation of the Processes of the Body.

Prof. W. H. Howell, of the Johns Hopkins University, delivered the presidential address in Section K (Physiology and Experimental Medicine). He summarised the present state of knowledge of the chemical regulation of the processes of the body by means of activators, kinases, and hormones. The chief points touched upon are as given in the following brief abstract.

In recent years we have come to understand that the complex of activities in the animal body is united into a functional harmony, not only through a reflex control exerted by the nervous system, but also by means of a chemical regulation effected through the blood or other liquids of the organism. Having referred to Brown-Séquard's generalisation, according to which every tissue of the body in the course of its normal metabolism furnishes material to the blood that is of importance in regulating the activities of other tissues, Prof. Howell said in recent years it has been re-stated in attractive form by Schiefferdecker in his theory of the symbiotic relationship of the tissues of the body. According to this author, we may conceive that among the tissues of a single organism the principle of a struggle for existence, which is so important as regards the relations of one organism to another, is replaced for the most part by a kind of symbiosis, such that the products of metabolism in one tissue serve as a stimulus to the activities of other tissues. From many sides and in many ways facts have been accumulating which tend to impress the general truth that the co-activity of the organs and tissues may be controlled through chemical changes in the liquid media of the body as well as through nerve impulses, but in physiology, at least, we owe the definite formulation of this point of view to Bayliss and Starling. Starling's convenient term of "hormone" as a general designation for such substances has served to give a wide currency to the conception.

In treating this subject one must consider also the more or less nearly related instances of combined activity of a chemical sort which are expressed by such terms as chemical activators, kinases, and co-ferments. These terms, like that of hormone, are relatively new; they have been brought into existence by investigators to explain or to express special reactions connected with metabolism, and particularly with the action of ferments. The word activator has reference to the fact, long known, that the ferments, or some of them, at least, are secreted in an inactive form, a proferment, which is activated or converted to an active form by a reaction with some definite substance produced elsewhere in the body.

The term kinase is used at present in animal physiology in connection with two reactions only. In both cases it refers to an activating process where the activator is a colloidal substance of unknown composition.

In addition to the activators of the inorganic and the colloidal type, there is perhaps a third kind of activation exemplified in the substances known as co-enzymes or co-ferments. This term may be used to define that kind of cooperative activity between an enzyme and some other non-colloidal substance which we see illustrated in the influence of the bile salts upon pancreatic lipase. The process differs from activation of a proferment to a ferment only in that the combination of the enzyme with its activator is dissociable instead of being permanent. By dialysis or otherwise the co-enzyme can be separated from the enzyme, and the action of the two may be tested separately or in combination. Starling defines hormones as chemical messengers which, formed in one organ, travel in the blood stream to other organs of the body and effect correlation between the activities of the organ of origin and the organs on which they exert their specific effect. Such substances belong to the crystalloid rather than the colloid class; they therefore are thermostable, and do not act as antigens when injected into the living animal.

NO. 2108, VOL. 83]

The substances of known composition which may be regarded as playing the rôle of hormones are few in number, three or four at most, as follows:—first, the carbon dioxide formed in the tissues, particularly in muscle during contraction; secondly, the adrenalin of the adrenal glands, which in some way, directly or indirectly, makes possible the full functional activity of the involuntary musculature of the body; thirdly, the hydrochloric acid produced in the stomach, which stimulates the formation of secretin in the duodenal epithelium; and, fourthly, possibly the iodothyron of the thyroid gland, with its dynamogenic effect upon the neuro-muscular apparatus of the body. In addition, there are a number of hormones of unknown composition which have been either proved or assumed to exist, and are held responsible for certain well-known correlations of function.

Method and Matter of Science.

Under the title "Science as Subject-matter and as Method," Prof. John Dewey, of Columbia University, in his presidential address to Section L (Education), introduced the question of how far the science teaching in schools has up to the present been educational in the true sense.

All, he said, who are much interested in securing for the sciences the place that belongs to them in education feel a certain amount of disappointment at the results hitherto attained. The glowing predictions made respecting them have been somewhat chilled by the event. Of course, this relative shortcoming is due in part to the unwillingness of the custodians of educational traditions and ideals to give scientific studies a fair show. Yet in view of the relatively equal opportunity accorded to science to-day compared with its status two generations ago, this cause alone does not explain the unsatisfactory outcome. Considering the opportunities, students have not flocked to the study of science in the numbers predicted, nor has science modified the spirit and purport of all education in a degree commensurate with the claims made for it. The causes for this result are many and complex. One influential cause, the remedy for which most lies with scientific men themselves, is that science has been taught too much as an accumulation of ready-made material with which students are to be made familiar, not enough as a method of thinking, an attitude of mind, after the pattern of which mental habits are to be transformed.

The infinitely extensive character of natural facts and the universal character of the laws formulated about them is sometimes claimed to give science an advantage over literature; but viewed from the standpoint of education, this presumed superiority turns out a defect; that is to say, so long as we confine ourselves to the point of view of subject-matter. Just because the facts of nature are multitudinous, inexhaustible, they begin nowhere and end nowhere in particular, and hence are not, just as facts, the best material for the education of those whose lives are centred in quite local situations and whose careers are irretrievably partial and specific. If we turn from multiplicity of detail to general laws, we find, indeed, that the laws of science are universal, but we also find that for educational purposes their universality means abstractness and remoteness.

One of the most serious difficulties that confronts the educator who wants in good faith to do something worthwhile with the sciences is their number and the indefinite bulk of the material in each. At times it seems as if the educational availability of science were breaking down because of its own sheer mass. There is at once so much of science and so many sciences that educators oscillate helplessly, between arbitrary selection and teaching a little of everything. Science teaching has suffered because science has been so frequently presented just as so much ready-made knowledge, so much subject-matter of fact and law, rather than as the effective method of inquiry into any subject-matter.

We define science as systematised knowledge, but this definition is wholly ambiguous. Does it mean the body of facts, the subject-matter? Or does it mean the processes by which something fit to be called knowledge is brought into existence, and order introduced into the flux of experience? That science means both of these things will doubtless be the reply, and rightly; but in the order both of time and of importance, science as method precedes

science as subject-matter. Systematised knowledge is science only because of the care and thoroughness with which it has been sought for, selected, and arranged. Only by pressing the courtesy of language beyond what is decent can we term such information as is acquired ready-made, without active experimenting and testing, science. The force of this assertion is not quite identical with the commonplace of scientific instruction that text-book and lecture are not enough—that the student must have laboratory exercises. A student may acquire laboratory methods as so much isolated and final stuff, just as he may so acquire material from a text-book. One's mental attitude is not necessarily changed just because he engages in certain physical manipulations and handles certain tools and materials. This problem of turning laboratory technique to intellectual account is even more pressing than that of utilisation of information derived from books. Almost every teacher has had drummed into him the inadequacy of mere book instruction, but the conscience of most is quite at peace if only pupils are put through some laboratory exercises. Is not this the path of experiment and induction by which science develops?

It must not be supposed that, in dwelling upon the relative defect and backwardness of science teaching, the intention is to deny its absolute achievements and improvements, but it must be pointed out that only to a comparatively slight extent has the teaching of science succeeded in protecting the so-called educated public against recrudescences of all sorts of corporate superstitions and silliness.

It is not to be expected that our schools should send forth their students equipped as judges of truth and falsity in specialised scientific matters; but that the great majority of those who leave school should have some idea of the kind of evidence required to substantiate given types of belief does not seem unreasonable. Nor is it absurd to expect that they should go forth with a lively interest in the ways in which knowledge is improved and a marked distaste for all conclusions reached in disharmony with the methods of scientific inquiry.

The future of our civilisation depends upon the widening spread and deepening hold of the scientific habit of mind, and the problem of problems in our education is therefore to discover how to mature and make effective this scientific habit. Mankind, so far, has been ruled by things and by words, not by thought, for until the last few moments of history humanity has not been in possession of the conditions of secure and effective thinking. Without ignoring in the least the consolation that has come to men from their literary education, it is not too much to say that only the gradual replacing of a literary by a scientific education can assure to man the progressive amelioration of his lot. Unless we master things we shall continue to be mastered by them; the magic that words cast upon things may indeed disguise our subjection or render us less dissatisfied with it, but, after all, science, not words, casts the only compelling spell upon things.

The modern warship seems symbolic of the present position of science in life and education. The warship could not exist were it not for science—mathematics, mechanics, chemistry, electricity supply the technique of its construction and management; but the aims, the ideals in the service of which this marvellous technique is displayed, are survivals of a pre-scientific age, that is, of barbarism. Science has as yet had next to nothing to do with forming the social and moral ideals for the sake of which she is used. Even where science has received its most attentive recognition, it has remained a servant of ends imposed from alien traditions. If ever we are to be governed by intelligence, not by things and by words, science must have something to say about *what* we do, and not merely about *how* we may do it most easily and economically; and if this consummation is achieved, the transformation must occur through education, by bringing home to men's habitual inclination and attitude the significance of genuine knowledge and the full import of the conditions requisite for its attainment. Actively to participate in the making of knowledge is the highest prerogative of man and the only warrant of his freedom. When our schools truly become laboratories of knowledge-making, not mills fitted out with information-hoppers, there will no longer be need to discuss the place of science in education.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

GLASGOW.—Committees of members and friends of the University have procured contributions amounting to some 1500*l.* for the purpose of commemorating the services of Dr. John Cleland, regius professor of anatomy from 1877 to 1909, and Dr. William Jack, professor of mathematics from 1879 to 1909, who retired last year. It has been decided to present to the University a portrait of Dr. Cleland, painted by Sir George Reid, with a replica for Mrs. Cleland; and a portrait of Dr. Jack, painted by Sir James Guthrie, and also a prize, to be awarded at intervals, for the best thesis on a mathematical subject approved for the degree of Doctor of Science during the preceding period.

The University Court and Senate have had under consideration a proposal, emanating from the general council of graduates, for the establishment within the University of an order of independent lecturers, analogous to *privat-docenten*, who should give courses of lectures qualifying for graduation, and duplicating those already given by the regular professors and lecturers. The new lecturers were to be provided with class-room accommodation, and were to depend for their remuneration on the amount of fees received from students attending their classes. After a prolonged discussion, in which the Senate expressed the opinion that the proposal was not likely to contribute to educational efficiency, and the finance committee that it would seriously disarrange the University funds, the Court decided that effect could not be given to the scheme under the existing constitution of the University.

The University Court has sanctioned the establishment of a new course of instruction in chemistry, including metallurgical chemistry, for students of engineering. The course will be given by Dr. Cecil H. Desch, and will extend over the first two terms of the session. The ordinary course by Prof. Ferguson will be attended by students of arts, medicine, and pure science. Dr. Desch announces a course in metallography during the summer session.

THE Civil Service Estimates in class iv. (education, science, and art), just issued as a White Paper, show a net increase for 1910-11 of 697,718*l.* over the figures for 1909-10. The total estimates of 18,651,483*l.* for the ensuing year include the following:—Board of Education, 14,064,677*l.*, increase 417,663*l.*; British Museum, 175,895*l.*, decrease 3333*l.*; scientific investigation, &c., 74,228*l.*, increase 9764*l.*; universities and colleges, Great Britain, and intermediate education, Wales, 218,100*l.*, increase 700*l.* Scotland: public education, 2,253,725*l.*, increase 106,434*l.*; Ireland: public education, 1,656,901*l.*, increase 34,980*l.*; endowed school commissioners, 925*l.*, increase 51*l.*; universities and colleges, 168,080*l.*, increase 139,930*l.*; Queen's Colleges, nil (last year 4700*l.*).

A DEPUTATION from the Trade Union Congress waited upon Mr. Runciman, President of the Board of Education, on March 17 to urge, among other matters, technical training in day-time classes, the raising of the school age, entirely free secondary education, and the appointment of a Royal Commission to inquire into the misappropriation of educational endowments. In replying, Mr. Runciman said he hopes that by next Session a Bill will be introduced which will deal partly with the raising of school age and partly with the question of day technical classes. If day technical classes are to be of much use, there must be pressure brought to bear on employers. All educationists desire to see the school age raised. Children who leave school at thirteen or fourteen know practically nothing about arithmetic or writing with ease. This deplorable state of things can be remedied in two ways, by raising the school age and by bringing the technical classes nearer to them. Trade unionists, he said, can do as much towards the advancement of education as Parliament can. Dealing with free places in secondary schools, Mr. Runciman said that, taking the whole of the secondary schools of this country in 1907-8, there were 2 per cent. more than the 25 per cent. standard, while in 1909-10 31 per cent. of the total places in the secondary schools were free places.

The State is making a change in many of the endowed charities which are scattered all over the country. In the course of time it will be possible, not only to apply the whole of the educational endowments to the original purposes of their founders, but to combine the small endowments so as to make them effective.

THE issue of the Journal of the Association of Teachers in Technical Institutions for January contains a paper by Mr. John Wilson, the president of the association, on the relation of the technical institution to the modern university. After commenting upon the advanced character of much of the teaching carried on in technical institutions, and mentioning the creditable amount of research work published yearly by the staffs and senior students of these schools and colleges, Mr. Wilson gave some interesting statistics as to the students who graduated in science at the University of London during 1909. It appears that altogether 292 candidates were awarded the degree of B.Sc., and that 57 of these studied entirely at technical institutions, while if the students who did part of their work at a technical institution are included, the number reaches 80. Mr. Wilson also gives the numbers of registered "internal" students and "recognised" teachers in London polytechnics, and compares the total with those in the case of certain other London colleges. During the session 1908-9, the number of registered internal students in the faculty of science was:—at University College, 224; King's College, 175; East London College, 162; and at eight "recognised" polytechnics, 372. In these eight polytechnics there are 94 "recognised" teachers of arts, science, and engineering. In other words, the polytechnics have become important centres of university work. Mr. Wilson maintains that the success of even the limited recognition of London polytechnics by the University of London clearly points to the desirability of the extension of that recognition by the University and to a widely increased measure of recognition of local technical institutions by the provincial universities.

At a meeting of the Royal Dublin Society on March 9 Prof. Senier delivered a lecture on "The University and Technical Training." From the account of the meeting in the *Irish Times* of March 10 we learn that Prof. Senier considered four types of institutions for the advancement and diffusion of learning and of its applications to society; institutions of acknowledged university rank or residential college universities, exemplified by Oxford; the research university, as seen at Berlin; the examination university, first known in Napoleon's University of Paris; and the technical research university, Charlottenburg. In England, he said, where numerous new universities have been established in recent years, the type adopted has been a combination of the German Research University and the German Technical Research University, the one or the other type predominating, according to local needs, and the whole adapted to its surroundings, particularly to the conditions of secondary education. Whatever view may be held respecting the German practice of separating these two types, as adapted to German conditions, Prof. Senier thinks that for the conditions which prevail in the British Isles the combination of the two in new universities is a wise arrangement. The two new universities in Ireland are also of this combined type, and are to be adapted to Irish educational conditions and the needs of the country. After directing attention to the influence Liebig exerted through his students in the direction of scientific research, Prof. Senier said so great is that influence that science laboratories after the model of Giessen have become the recognised attribute of science professorships throughout the world. Another advantage possessed by the German university is the character of the leaving examination of the secondary school. It corresponds to a matriculation examination, with the added knowledge acquired by about two years' university study in arts, and its acceptance by the university as evidence of sufficient knowledge for matriculation relieves the university of the practice of giving the student an examination as his first experience on entering. In Prof. Senier's opinion secondary schools should abandon all attempts to teach experimental science. To rival the work of the German universities the better organisation and coordination of the entire educational

system is necessary. Germany has built up a chemical industry with tens of millions of pounds annually through the agency of research chemists, methodically trained in technical schools. German manufacturers know the value in dividends of the services of trained research chemists; Irish and English manufacturers do not.

SOCIETIES AND ACADEMIES.

LONDON.

Physical Society, February 25.—Prof. H. L. Callendar, F.R.S., president, in the chair.—Prof. J. Perry: Telephone circuits. The author published a paper in the Proceedings of the society in 1893 showing how voltage v and current c are attenuated along a telephone or submarine telegraph line, a line with resistance r , capacity k , inductance l , and leakage s per unit length; currents are of the form $\sin qt$. When lq/r is considerable the mathematical expressions become simple. It was pointed out that the introduction of l is of great benefit. The author now points out that k may be made negative by the use of inductance leaks to earth, and l may be made negative by the use of condensers in series with the line. To introduce l , as Mr. Pupin has done, by inductance coils at equidistant places on the line, or to introduce the other properties mentioned by placing other contrivances at equal distances, is a mathematical problem of great complexity. Contrivances placed close together have the same effect as the continuous distribution of properties, but there is considerable expense; the problem is to find how far apart the contrivances may be placed so that the effect produced shall still be beneficial. Mr. Pupin has given a rule for the spacing of his coils, but practical men dispute its accuracy; nobody has given a rule for other contrivances; the object of the author is to give an easy method of calculation which is practically correct, and can be used when the contrivance is any network or other combination of resistances, inductances, and capacities—some being leaks to earth—and it may include transformers, motors, and generators. Suppose there are contrivances at the equidistant places A, B, &c., m miles apart in a cable which has the above-mentioned properties r , k , l , and s . There is a contrivance the terminals of which are A and A₀, another the terminals of which are B and B₀; between A₀ and B there is m miles of cable. Let the currents in the line at A, A₀, and B be c , c_0 , and C. Let the voltages at these points be v , v_0 , and V. The assumption on which the whole method is based is that $V/C = v/c = \rho$. This is practically true everywhere in a long line except near the ends. Now whatever be the nature of the contrivance, we can calculate v_0 and c_0 from v and c . It is also known that

$$V = v_0 \cosh mn + \frac{r + lqi}{n} c_0 \sinh mn,$$

$$C = c_0 \cosh mn + \frac{n}{r + lqi} v_0 \sinh mn,$$

when

$$n = \sqrt{(r + lqi)(s + kqi)}.$$

Putting V/C or ρ equal to v/c , we have a quadratic to calculate ρ , and therefore V and C, and the problem is solved. Taking $c = \sin qt$ and calling it 1, then $v = \rho$. Whatever the contrivance may be, we find that $V = a + b\rho$ and $C = a + b\rho$, where a , β , a , and b are given in value; they are usually unreal quantities of the form $M + Ni$, where i is $\sqrt{-1}$. Solving for ρ , and finding C, we have two answers which are reciprocals of one another. If $\frac{1}{2}(a + \beta)$ be called P, and this is very easily evaluated, then

$$C = P \pm \sqrt{P^2 - 1}$$

Examples of the use of the method are given, some showing that the detached contrivances produce much the same and others very different effects from what might have been expected from a study of the cable with continuous properties. It was shown that a line may have contrivances somewhat far apart which will tune it to a musical note merely, so that it acts almost like an ohmic resistance, but which will not transmit well the currents of other frequencies, and that for the commercial transmission

of speech there must be a compromise. The author laid stress upon the fact that his method of calculation could be taught to quite non-mathematical people.—Prof. C. H. **Loes**: The laws regarding the direction of thermo-electric currents enunciated by M. Thomas.—H. R. **Nettleton**: New method of determining thermal conductivity.

Mineralogical Society, March 15.—Prof. W. J. Lewis, F.R.S., in the chair.—G. W. **Grabham**: A new form of petrological microscope, with notes on the illumination of microscopic objects: The new instrument, which is of the "Dick" or "English" pattern, has a focussing sub-stage carrying a series of condensers mounted on a triple nose-piece, each capable of being inserted in the axis of the instrument. A new explanation was given of the "Becke" or bright-line effect, especially applicable to parallel polarised light traversing mineral sections, which meet along inclined junctions.—W. F. P. **McIntock**: Datolite from the Lizard district. Datolite, which is associated with calcite, chalcopyrite, and natrolite (rare) in veins and geodes at the junction of the serpentine and hornblende schist, Parc Bean Cove, Mullion, Lizard district, Cornwall, occurs in crystals measuring up to 2 cm. along the *b* axis, and displayed fourteen forms, of which two were new. An analysis gave SiO_2 , 37.45; CaO , 34.67; Fe_2O_3 and Al_2O_3 , 0.57; B_2O_3 , 21.87; H_2O , 5.67; total, 100.23.—Arthur **Russell**: Additional notes on the occurrence of zeolites in Cornwall and Devon. The occurrence of heulandite, a mineral hitherto not recorded from Cornwall, at Carrick Du Mine, St. Ives, Cornwall, was described; also of chabazite and heulandite at the Ramsley Mine, South Tawton, Devon.—Dr. J. W. **Evans**: A modification of stereographic projection. Faces below the plane of projection are represented by the same points as parallel faces above it, upper faces being distinguished by a plus, and lower faces by a minus, sign.—Dr. J. W. **Evans**: Axes of rotatory symmetry. Coincidence is complete or codirectional when equivalent lines and their directions coincide, incomplete or contradirectional when equivalent lines coincide, but equivalent directions of unimimal lines are opposed; in both cases it is colinear. If a minimum rotation of $2\pi/n$ result in codirectional, unidirectional, or colinear coincidence, the axis of rotation has codirectional, contradirectional or colinear symmetry, with cyclic number *n*.—Prof. H. L. **Bowman** exhibited models illustrating space-lattices and Sohncke's point-systems.

DUBLIN.

Royal Dublin Society, February 22.—Mr. R. M. Barrington in the chair.—Prof. W. **Brown**: Chrome-steel magnets. Light steels containing from 1.75 to 9.22 per cent. of chromium were tested for magnetic moment per gram, the best result being obtained with a magnet which contained about 2.5 per cent. of chromium.—W. J. **Lyons**: The distribution of mean annual rainfall over the counties of Dublin, Wicklow, Kildare, and Meath. The rainfall over this area varies from below 28 inches to probably more than 60 inches in a very marked manner, closely related to the very striking orographical features of the area. The author suggested that the recognised action of hills in inducing condensation by causing ascensional currents was not an adequate explanation of the marked increase found in the rainfall of hilly districts. He thought it probable that mountains facilitated the processes of rain development, apart from any influence on condensation.—Prof. F. **Barrett**: A simple form of open-scale barometer. In form this instrument resembles an air thermometer, only that it indicates variations of atmospheric pressure and is almost insensible to changes of temperature. This is accomplished by making use of a Dewar's liquid-air flask as the air receptacle, into which is sealed a quill glass tubing containing an index of a dense non-conducting liquid. The tube is open to the air at one end, and is sealed into a wider glass tube which surrounds it, and from which the air has been exhausted as completely as possible. It is found in practice that the readings correspond fairly well with those of an ordinary barometer, and as it can be made as sensitive as desired by altering the ratio of the capacities of the bulb and index tube, it is adapted for domestic use as a weather-glass, and claims to be nothing more.

PARIS.

Academy of Sciences, March 14.—M. Émile Picard in the chair.—Henri and Jean **Becquerel** and H. Kamerlingh **Onnes**: The phosphorescence of uranyl salts at very low temperatures. The changes observed in the absorption spectra at temperatures down to that of liquid air have been described in a previous paper. In the present paper details of the spectra are given for the temperatures of 80° C. absolute (boiling nitrogen) and 14° C. absolute (solid hydrogen). The bands approach asymptotically a limiting position as the temperature is lowered. A very strong magnetic field (35,000 Gauss) is without influence on the spectra. Ordinary phosphorescent spectra appear to be due to the effect of traces of impurities in the phosphorescent substance; this is not the case with uranyl salts; the spectra appear to be due to the uranium itself.—H. **Deslandres** and P. **Idrac**: The spectrum of the comet 1909a. The arrangement of the spectrograph used is described, and the wave-lengths of the lines observed given. The bands of hydrocarbons and cyanogen were identified.—J. **Boussinesq**: The vertical propagation, at great depths, of the movement of waves by emersion in the case of a canal or basin indefinite horizontally.—MM. **Haller** and Ed. **Bauer**: The alkylation of the fatty ketones by the use of sodium amide. The decomposition of the hexa-alkylketones. Diethylketone has been methylated by sodium amide and methyl iodide, ethyl-isopropylketone, di-isopropylketone, a high boiling condensation product, and tetramethyl-ethylketone, being produced. The hexa-alkylacetones are split up by sodium amide, a trialkylmethane and trialkylacetamide arising from the reaction.—Prof. Hittorf was elected a foreign associate.—Charles **Nordmann**: The absorbing atmospheres and the intrinsic luminosities of some stars.—Jules **Baillaud**, J. **Chateau**, and M. **Giacobini**: Observation of a minor planet at the Observatory of Paris. The traces of this planet were first noticed by Jules Baillaud on a negative of the international chart of the sky taken on March 3. Observations are tabulated for March 3, 5, 7, 8, 10, and 11.—Frédéric **Riesz**: Certain systems of functional equations and the approximation of continued functions.—L. **Remy**: The algebraic surfaces representable on that of Kummer.—H. **Larose**: The equation of telegraphists.—E. **Estanave**: The simultaneous production of stereoscopic relief and of changing aspect in the photographic image.—Pierre **Weiss** and Kamerlingh **Onnes**: The saturation intensity of magnetisation at very low temperatures. The intensities of saturation have been measured at the ordinary temperature and at the temperature of boiling hydrogen (20° C. absolute) for nickel, iron, and magnetite. The results for cobalt were not satisfactory.—Pierre **Weiss** and Kamerlingh **Onnes**: The magnetic properties of manganese, vanadium, and chromium. For these metals at the temperature of solid hydrogen (14° C. absolute) there was expected either the appearance of ferromagnetic phenomena or a paramagnetism considerably increased according to Curie's law. It was found experimentally that neither of these effects was produced, the magnetic phenomena remaining very slight. The theoretical consequences of these facts are discussed.—P. **Vaillant**: A particular case of evaporation. A study of the diffusion of the vapour arising from a liquid in a cylindrical tube the length of which was great in proportion to its diameter.—Ch. **Féry**: A new reflectometer. A hemispherical cavity is formed in a block of plane glass, and the hole exactly filled by a hemispherical block of glass of the same curvature. The drop of liquid the refractive index of which is to be measured is placed between the two blocks, and the radius of the dark ring formed by total reflection measured. From this and the corresponding radius of the dark ring when air is between the two blocks the index of refraction can be determined with an accuracy of about 0.005.—L. **Blösch**: Chemical actions and ionisation by bubbling. It is shown that the ionisation produced when gases are evolved from a liquid is the result of actions in the liquid surface.—O. **Boudouard**: The testing of metals by the study of the damping of vibratory movements.—M. **Väres**: The analysis of essence of turpentine by curves of miscibility. The author's results generally confirm those of M. Louise, but some differences are pointed out.—M. **Lecoq**: A colloidal solution of pure metallic arsenic. A colloidal

solution of arsenic can be obtained by the electrolysis of an alkaline solution with arsenic for the anode, or by the electro-reduction of an alkaline solution of arsenious acid. The properties of the solutions thus obtained are described in detail.—**J. B. Senderens**: The catalysis of the aromatic acids. A study of various catalytic substances shows that only thoria, zirconia, and green oxide of uranium are of practical use in this reaction, and of these thoria has the preference. More than thirty aromatic mixed ketones have been obtained by the application of this reaction.—**F. Couturier**: The stability of the β -keto-aldehydes.—**G. Darzens**: A new method of synthesis of unsaturated ketones. Stannic chloride can replace aluminium chloride with advantage in reactions between acetyl chloride and hydrobenzenes. The experiments described have a bearing on the theory of the Friedel and Crafts reaction.—**G. Malfitano** and **Mlle. A. Moschhoff**: The coagulation of starch material by freezing.—**L. Ravaz**: Researches on the specific reciprocal influence of the subject on the graft in the vine.—**G. André**: The development of a bulbous plant: variations in the weight of nitrogen and the mineral matters.—**M. Biéler-Chatelean**: The estimation of assimilable potash in soils. It is concluded that the amount of potash extracted by a solution of carbon dioxide in water gives results that are best comparable with the actual culture experiments.—**J. Tissot**: The experimental study of intra-organic combustions in animals breathing air progressively deprived of oxygen, and the natural methods of defence of the organism against anoxihæmia.—**F. Maignon**: The influence of the genital glands on glycogen production.—**M. Ranjard**: Contribution to the study of audition and its development by the vibrations of the vowel siren.—**H. Dominici**, **G. Petit**, and **A. Jaboin**: The persistent radio-activity of the organism resulting from the intravenous injection of an insoluble salt of radium, and on its applications. One milligram of radium sulphate was injected into a horse, and the distribution of the radio-activity studied. The effects could be traced for more than six months after the date of the injection.—**Mlle. Cernovodeanu** and **Victor Henri**: The action of the ultra-violet rays on micro-organisms and on different cells. Microchemical study. The ultra-violet rays produce chemical and physical transformations in protoplasm which modify completely all the colour reactions. This action of the rays is quite different from that of heat, hydrogen peroxide, or ordinary fixing agents.—**J. Nageotte**: The activity of the myeline sheath in nerves separated from the organism.—**H. E. Sauvage**: The Andersh ganglion in the horned Phrynosome.—**P. Hachet-Souplet**: The education of animals by man as a means of psychological research.—**L. Bordas**: General considerations on the Malpighi tubes of the larvæ of Lepidoptera.—**Paul de Beauchamp**: The existence and conditions of parthenogenesis in *Dinophilus*.—**A. Rodet** and **M. Lagriffoul**: The serotherapy of typhoid fever. Clinical results. In the greater proportion of the cases cited the disease has been arrested at the twelfth day or later. If the serum is administered at the eleventh day, at the latest, it appears to exert a beneficial influence on the course of the disease.—**A. Trillat** and **M. Sauton**: The influence of vitiated atmospheres on the vitality of microbes.—**P. and N. Bonnet**: The existence of the Trias and Mesojurassic in the neighbourhood of Djoulfa, southern Transcaucasia.—**Const. A. Ktenas** and **Ph. Négris**: The presence of layers containing Ellipsactinia in the Vardusa mountains and in *Ætolia*, in Greece.—**Albert Michel Lévy**: The pechstein strata in the Esterel.—**Albert Nodon**: Researches on terrestrial magnetism.—**Henryk Arctowski**: Some anomalies in the distribution of atmospheric pressure in the United States.

FORTHCOMING CONGRESSES.

MAY 16-27.—International Congress of Americanists. Buenos Ayres. General Secretary: Dr. Lehmann-Nitsche, Calle Viamonte 430, Buenos Ayres, Argentine Republic.

MAY 14-22.—International Botanical Congress. Brussels. General Secretary: Dr. E. de Wildeman, Jardin botanique, Bruxelles.

JUNE.—International Congress of Mining, Metallurgy, Applied Mechanics and Practical Geology. Düsseldorf. General Secretaries: Dr. Schrödter and Mr. Löwenstein, Jacobi-strasse 3/5, Düsseldorf, Germany.

JULY 27-31.—International Congress on the Administrative Sciences. Brussels. Secretary of British Committee: Mr. G. Montague Harris, Caxton House, Westminster.

AUGUST 1-6.—International Congress of Entomology. Brussels. Chairman of Local Committee for Great Britain: Dr. G. B. Longstaff, Highlands Putney Heath, S.W.

AUGUST 1-7.—French Association for the Advancement of Science. Toulouse. President: Prof. Gariel. Address of Secretary: 28 rue Serpente, Paris.

AUGUST.—International Congress of Photography. Brussels. Correspondent for United Kingdom: Mr. Chapman Jones, 11 Eaton Rise, Ealing, W.

AUGUST.—International Congress of School Hygiene. Paris. Secretary: M. Dufestel, 10 Boulevard Magenta, Paris.

AUGUST 15-20.—International Zoological Congress. Graz (Austria). President: Prof. Ludwig von Graff. Address for inquiries: Präsidium des VIII. Internationalen Zoologen-Kongresses, Universitätsplatz 2, Graz (Österreich).

AUGUST 18-26.—International Geological Congress. Stockholm. General Secretary: Prof. J. G. Andersson, Stockholm 3.

AUGUST 31 TO SEPTEMBER 7.—British Association. Sheffield. President: Prof. T. G. Bonney, F.R.S. Address for inquiries: General Secretariat, Burlington House, W.

SEPTEMBER 6-8.—International Congress of Radiology and Electricity. Brussels. General Secretary: Dr. J. Daniel, 1 rue de la Prévôte, Brussels. Correspondents for United Kingdom: Prof. Rutherford and Dr. W. Makower, University of Manchester, and Dr. W. Deane Butcher, Holyrood, Ealing, W.

SEPTEMBER 18-24.—German Association of Naturalists and Physicians. Königsberg. Secretaries: Prof. Lichtheim and Prof. F. Meyer, Drummstr. 25-29, Königsberg.

SEPTEMBER 27-30.—International Physiological Congress. Vienna. President: Prof. S. Exner. General Secretary for United Kingdom: Prof. E. B. Starling, University College, London, W.C.

OCTOBER 6-12.—Congrès International du Froid. Vienna. Correspondent for United Kingdom: Mr. R. M. Leonard, 3 Oxford Court, Cannon Street, E.C.

THURSDAY, MARCH 31, 1910.

A FRENCH TREATISE ON PHYSICAL GEOGRAPHY.

Traité de Géographie physique: Climat, Hydrographie, Relief du Sol, Biogéographie. By Prof. Emmanuel de Martonne. Pp. viii+910, and maps. (Paris: Librairie Armand Colin.) Price 22 francs.

EVERY writer of text-books is faced by the difficulty that the science of which he treats inosculates with and is overlapped by other branches of science. One of his most important tasks, therefore, consists in the exercise of a wise judgment as to what should be properly included, and what excluded, in the treatise he is preparing.

It has sometimes been suggested that all science may be regarded as falling into the two divisions geography and astronomy, the former dealing with everything that relates to our own planet, the latter with matters concerning the outside universe. But however logical such a scheme of classification of the sciences may be regarded, it cannot be commended on the score of convenience. There is no branch of physical or natural science which is not a part of "earth-knowledge," but it would be clearly impossible in a single treatise to deal with the foundations and superstructures of physics, chemistry, geology, botany, zoology, and anthropology. A work on geography must take for granted a certain amount of preliminary knowledge of science, and be contented with showing their application to the explanation of the various phenomena exhibited on the surface of the globe.

In the preface to the work before us, its author suggests as natural divisions of physical geography the following:—Morphologie, l'hydrographie, le climat, la biogéographie, et la géographie humaine; and the bulky volume now issued deals only with the first four of these divisions. The author justly remarks that it is almost impossible for any man to have a complete personal knowledge of all these subjects, but that specialisation becomes necessary; he has therefore sought and obtained assistance from various colleagues and friends in dealing with different departments of the subject.

In the first division of the work, devoted to general notions on the subject, a clear account, occupying 25 pages, is given of the history and evolution of geological science, and in this part, as in all following divisions, a very useful and complete bibliography of the subject is supplied. The question of projection is fully treated, and, for the very numerous maps of the whole globe given throughout the work, the conventional system of Molweide (or Babinet) is adopted in preference to that of Mercator, thus avoiding the extreme polar distortions of the latter system.

The 160 pages devoted to meteorology, and constituting the second division of the work, contains an excellent summary of that branch of science. The chief meteorological instruments are described, and clear statements given on the temperature, the hygroscopic characters, and the movements of the atmosphere in different areas; and the bearings of these several

factors in producing different types of climate are discussed with much skill.

The subject of hydrography has more than 100 pages devoted to it, and constitutes the third division of the book. A good *résumé* of the observations made in recent years in the deep oceans is given with abundant references, including those to the latest published works. This is followed by chapters on the movements of the oceanic water, on the lakes, and on the rivers of the globe.

The fourth part of the work, dealing with the forms of the great land masses of the globe, constitutes the largest division of the book, occupying no fewer than 340 pages. After a sketch of the methods employed in surveying and of the different ways of representing the results on maps, a list is given of the chief published topographical maps of different parts of the world. We notice here some singular omissions. The Ordnance maps of England and Wales and of Scotland, on the one-inch scale, are referred to, but there is no mention of the existence of maps on other scales, or of any of the Ordnance maps of Ireland! The maps of the trigonometrical survey of India are included, but no notice is taken of any British colony, although Algeria and Tunis receive full consideration. This is a matter which certainly calls for rectification in a future edition.

The forms of the land surfaces resulting from different kinds of erosion are dealt with somewhat fully on the lines rendered familiar by the writings of Prof. W. M. Davis. Under the title of palæogeography a chapter is devoted to the forms and dimensions of land-masses during former geological periods, and the somewhat problematical questions connected with the subject are dealt with in considerable detail. The map of "Gondwanaland" on p. 587, in which the great continent of Permo-Carboniferous times is made to include, not only India and a large part of Africa, but to extend over Australia and the western half of South America, will naturally excite criticism from those who believe in the permanence of ocean-basins; as will also the map of the world in Cenomanian times, in which, following de Lapparent, Haug, and Frech, the author represents a northern and a southern Atlantis, and, more doubtfully, a Pacific continent. The chapters on glacial and desert conditions, and the surface features resulting from them, are fully up to date, and contain much useful information of a kind not usually found in text-books.

In the 180 pages devoted to "biogeography" there is much useful information included, but opinions will differ as to how far much of this matter should legitimately form a part of a treatise on physical geography. Such subjects as commensalism in plants and animals, the fertilisation of plants, domestication and its influence, mutation and saltation—important as they undoubtedly are—seem scarcely to form a portion of geographical science, and if they are included it is difficult to understand why many similar questions are omitted.

Apart from this difficult question of the limits which the author should adopt for his subject, the work before us is a mine of information, and especial praise

must be given to the great wealth of useful illustrations it contains. These include 396 figures and maps in the text, 48 plates with very beautiful photographs of scenery, &c., and two folding coloured maps.

J. W. J.

THE PREHISTORIC EVOLUTION OF ITALY.

The Stone and Bronze Ages in Italy and Sicily. By

T. Eric Peet. Pp. 528; maps and plates. (Oxford: Clarendon Press, 1909.) Price 16s. net.

THIS book gives a clear and exhaustive description of the results of the numerous excavations made by Italian archaeologists and a critical discussion of the material obtained. The author succeeds in giving a remarkably complete record of the evolution of culture in Italy from the Palæolithic age down to the Iron age. In arriving at his conclusions he relies almost entirely on technological data, which, though of great value in determining the state of culture of the peoples with which he deals, are of much less value than the data of physical anthropology in solving racial problems. Large numbers of skeletons appear to have been discovered in the immense number of tombs that have been investigated by the Italian archaeologists, but only in two or three cases does the author give us the measurements of these skeletons. As a result, many problems have to be left unsolved which with the assistance of physical data would apparently be easily soluble. For instance, a type of Neolithic pottery is found in a cave at Villafraati, in north Sicily, which differs from the Neolithic types found in other parts of the island, and has analogies with pottery found in certain neighbouring countries. The author is unable to decide whether this pottery was introduced by the immigration of a new race or by trade intercourse with foreign countries. He appears to have overlooked the important fact, mentioned by him in a footnote, that four skulls having an average index of 82.2 were found in the same cave as the new type of pottery. Knowing that the average index of the ancient Mediterranean race is 74-75, the physical anthropologist would have no hesitation in saying that the probability was immensely in favour of the new type of pottery being introduced into Sicily by the immigration of a new race.

The difference in the technique of the Neolithic implements and pottery in north and south Italy leads the author to the conclusion that the populations of these regions were two branches of the Mediterranean race who arrived in Italy by different routes. The southern branch almost certainly came by sea from Crete; about the route of the northern branch there is not the same certainty. Towards the end of the Neolithic period, pottery of the "dolmen" type appeared in south Italy, north Sicily, and Sardinia, and superseded the older types.

In the period coming after the Neolithic, which the author, following the Italian archaeologists, calls the Eneolithic period, copper makes its appearance alongside of stone. The rock-hewn tomb is introduced in south Italy and Sicily, and a great advance takes place in the technique of stone implements. Several

new types of pottery appear. One of these is distinctly Ægean, so there can be no doubt that there was trade intercourse in the Eneolithic period between Crete and south Italy and Sicily.

A remarkable type of pottery occurs in the early Eneolithic period in south-west Sicily in association with rock-hewn tombs. The ornamentation consists of rectilinear patterns painted in black on a ground of "white slip," with which the clay pot is coated. The distribution of this pottery is interesting; it is not found in Crete, but it has been found in Thessaly and in other parts of north Greece; fragments have also been found at Molfetta, in Apulia, south Italy. It looks, therefore, that there was a second route of trade or of migration from the east, across north Greece, the Adriatic, and south Italy to Sicily, which is quite distinct from the Ægean sea route along which the greater part of the trade of south Italy with the east, passed.

The author leans to the view that the great cultural changes of the Eneolithic period were not due to the immigration of a new race, but to foreign influence. Measurements of skulls found associated with the "painted white slip" were might possibly change this opinion. The average cephalic index of four skulls found at Castelluccio with this ware was 77.9, which looks significantly higher than that of the Mediterranean race.

The Bronze age in Italy is treated topographically. A very painstaking and up-to-date description is given of the material found in the lake dwellings, in the Terremare, and in Bronze-age hut-settlements and caves of north Italy. Chapters are then devoted to the Bronze age in south Italy, and to the Bronze age in Sicily and Sardinia.

In a chapter on the racial problem, the author deals with the racial affinities and origins of the peoples who introduced bronze into Italy. There are two theories in the field, that of Brizio and that of Pigorini. The author favours the latter. According to Pigorini's theory, the hut villages and caverns of the Neolithic age in north Italy were inhabited by a dolichocephalic race (called usually *Ibero-Liguri*) who inhumed their dead. At the end of the Neolithic period a new race appeared in north Italy which cremated its dead. This race planted the first lake dwellings in Lombardy. In the full Bronze age another branch of the same race invaded the eastern district of north Italy, and planted the lake dwellings of the Veneto and the Terremare of Emilia. At the end of the Bronze age, part of the new people crossed the Apennines and entered Tuscany and Latium. This new people Pigorini calls the *Italic*i. He considers that they were of the same race as the Swiss lake dwellers, and therefore probably brachycephalic. There is no direct evidence of this, as cremation was an invariable burial custom among the Italian like dwellers and the Terremare folk.

The volume is well printed, contains many excellent illustrations, and four valuable maps showing the distribution of sites in the Neolithic, Eneolithic, and Bronze ages. No student of the prehistory of man in Italy, or indeed in Europe, can dispense with read-

ing this volume. It is, we believe, the first treatise in English which has fully utilised the remarkable archæological discoveries of the last decade in Mediterranean countries, and the author is to be congratulated on the thoroughness and ability with which he has accomplished his task. J. G.

BOTANICAL PHOTOGRAPHS.

Vegetationsbilder. Seventh series. Parts iii. to viii. Part iii., *Der nördliche Schwarzwald*, by Otto Feucht; part iv., *Vegetationsbilder aus Dalmatien*, by L. Adamović; part v., *Charakterpflanzen des abessinischen Hochlandes*, by Felix Rosen; parts vi. and vii., *Pflanzenformationen aus Ost-Bolivia*, by Th. Herzog; part viii., *Vegetationsbilder aus Dänisch-Westgrönland*, by M. Rikli. Price 4 marks, each part containing 6 photographs. Edited by Prof. G. Karsten and Prof. H. Schenck. (Jena: Gustav Fischer, 1909-10.)

THIS unique botanical publication is being continually extended, so that a seventh series is now completed. The first double part of the volume, dealing with the colonisation of volcanic lands in Java and Sumatra, has been previously noticed. The third part is devoted to the vegetation of the northern area of the Black Forest, which is characterised by its coniferous trees and moorland. A typical bit of high moor shows bushes of *Pinus montana*, clumps of *Scirpus caespitosus* and tufts of *Juncus squarrosus*. On another plate the same pine is seen as a tall tree, contrasting with the adjacent Scots pine and spruce. The author has also been very successful with his representations of the two subalpines, *Andromeda polifolia* and *Athyrium alpestre*, and of the umbellifer, *Meum athamanticum*. Dr. L. Adamović has brought together a most attractive set of photographs from the sunny climate of Dalmatia. They illustrate a strip of shore and rocks of the littoral, sublittoral and montane regions. So carefully have the spots been chosen and the photographs taken that the author can point out most of the individual plants. Especially charming is the first plate, showing *Aster Tripolium* with species of *Statice* and *Inula crithmoides* on the shore, and the second picture of sublittoral rock where *Dianthus dalmaticus* and *Iris germanica*, with other plants, are easily recognised. Trees provide the chief feature of the views on the Abyssinian plateau. The rosaceous plant *Hagezia abyssinica*, which tardily assumes its arboreal shape, is very striking; the unripe fruits are esteemed by the natives as a valuable specific for internal complaints. A fine specimen of tree *Euphorbia* is depicted, which the author suggests may have developed an arboreal form when it passed from a dry to a moist climate. Even more singular is the tree *Lobelia*, formerly known as *Rhyncho-petalum*. Illustrations are also given of a huge spreading *Ficus* and a tree *Entada*.

Dr. Th. Herzog has provided a fine double part relating to the remote territory of East Bolivia. Along the Paraguay, on savannah land subject to inundations, is the home of the wax palm, *Copernicia cerifera*, where it is associated with tall grasses, species of *Paspalum* and *Andropogon*. Another plate represents

the growth of the palm *Acrocomia Totai*, on the sandstone highlands of Chiquitos. A "monte" or thicket formation occurs on parts of the plain of the Rio Grande, where thorny scrub and succulents predominate; the plates depict species of *Cereus*, a *Trithrinax* and the bromeliad *Aechmea polystachya*, which last is valuable to travellers, as it generally holds a store of water. Other palms selected for illustration are *Orbignya palmata* and *Mauritia vinifera*, typical of the savannahs, *Astrocaryum Chonta* and *Iriarte exorrhiza*, denizens of the rain forests; *Iriarte* produces remarkable thorny prop roots. The last two plates portray succulents, of which *Pilocereus celsianus* is the most striking, on account of its silvery crown of hairs.

The concluding part contains some typical aspects of vegetation in Danish West Greenland. In the southern area birches alone attain to the height of trees as seen in the first plate; the second indicates the importance of *Salix glauca*. A brilliant photograph of an Arctic meadow would be better appreciated if a key to the plants had been supplied. There is an effective photograph of cotton-grass growing by the edge of a lake, and another of clumps of *Glyceria distans* which attract attention on account of the peculiar lie of the stems.

MAGNETIC CHARTS.

Magnetische Kartographie in historisch-kritischer Darstellung. By G. Hellmann. Veröffentlichungen des Kgl. Preuss. Meteorologischen Instituts, Abhandlungen, Bd. iii., Nr. 3. Pp. 61. (Berlin: Behrend and Co., 1909.) Price 6 marks.

DR. G. HELLMANN, as head of the Prussian Meteorological Institute, which controls the magnetic observatory at Potsdam, and as a lover and collector of antique magnetic literature, is conspicuously qualified for the work he has undertaken in the present volume. It aims at giving a complete list of all magnetic charts of any importance. All time prior to the year 1700 is regarded by Dr. Hellmann as preceding the era of charts, but he devotes a few pages to Columbus and other pioneers, whose work relates to the discovery that the magnetic needle is usually inclined to the geographical meridian.

Time since 1700 is divided into two periods. The first, extending until 1835, was heralded in by the famous chart of Halley; it is briefly discussed on pp. 10-11. The second period, extending from 1835 to the present day, saw the introduction of magnetic surveys on land.

The earliest work of this kind, according to our author, took place in England on the initiative of the British Association. On pp. 11-17 there is an enumeration of all the principal land surveys; while pp. 18-27 summarise the present state of our knowledge of the distribution of the magnetic elements. There is a useful list on p. 26 of the epochs of the principal surveys since 1891, with particulars as to the number and density of distribution of the stations. A number of propositions are laid down in pp. 28-29 as to the objects to be aimed at in magnetic surveys and other work preliminary to the construction of

charts. The author considers it most important that the exact observational work at sea commenced under the auspices of the Carnegie Institution should be extended as soon as possible to all seas. He advocates international cooperation to ensure continuity in the drawings of magnetic lines in frontier districts, and emphasises the importance of adequate determinations of secular change.

The terminology, units, &c., employed in the description of the charts are explained in pp. 30-31. The charts themselves are divided into those dealing with the whole or the greater part of the earth, those confined to the oceans, those dealing with the several continents, and, finally, those devoted to individual countries or districts. The information given usually includes the area, the epoch, the magnetic element or elements dealt with, the interval—in specified units—between the successive isogonal, isoclinal, or isomagnetic lines, the geographical scale of the map, also the locus and date of publication. The title in each case, when there is one, is given in the original language. There is a separate list on pp. 60-61 of charts based on theory.

The list of charts seems very complete. As evidence that it is up to-date may be mentioned the fact that it includes the British and American world charts published respectively in 1906 and 1907, Commander Chetwynd's charts of the South Polar regions published in 1908, Dr. Schmidt's charts of North Germany, and Prof. Beattie's South African charts published in 1909. The volume is clearly printed in good-sized type, and should prove a valuable work of reference.

C. CHREE.

ELECTRICAL BIOGRAPHY.

Makers of Electricity. By Brother Potamian and Prof. James J. Walsh. Pp. vi+404. (New York: Fordham University Press, 1909.)

THIS is not a work on central-station engineers, but a series of biographical sketches of the chief pioneers in the science of electricity in its historical development. Of these sketches there are twelve, as follows:—Peregrinus and Columbus; Norman and Gilbert; Franklin and some of his contemporaries; Galvani; Volta; Coulomb; Oersted; Ampère; Ohm; Faraday; Clerk Maxwell; Lord Kelvin. As the first three, together with those on Oersted and Lord Kelvin, are signed by Brother Potamian, it may be assumed that the rest are by his colleague, Dr. Walsh, who is the author of several others works, "Makers of Modern Science," "Catholic Churchmen in Science," "Makers of Modern Medicine," and "The Popes and Science," which appear to have a great vogue amongst Roman Catholic readers in the United States. Brother Potamian, better known to his English friends as Dr. O'Reilly, is one of those who has made the bibliographical history of electricity his own; and his masterly annotations of the catalogue of the Wheeler collection of electrical books (formerly the library of the late Mr. Latimer Clark) in the possession of the American Institute of Electrical Engineers show him to possess abundant qualifica-

tions for writing biographies of the pioneers. If the chapters on Peregrinus and Columbus, Norman and Gilbert, add nothing to previous knowledge, they are valuable in presenting very readable summaries of the results of recent antiquarian research into the achievements of these early investigators of magnetism. The account of Peregrinus is particularly good, and avoids errors too often attaching to accounts of his long-forgotten discoveries. The article on Gilbert is also replete with the details which have been unearthed in recent years, though by a slip on p. 49 he is said to have blamed Stevinus for certain "vain and absurd" views about the variation of the compass in southern regions of the earth. It was not Stevinus whom he blamed, but "certain unnamed Portuguese mariners." Gilbert's Copernican views are discussed fully, and criticised.

Franklin's work in electrical observation is treated at some length, as is natural in a work intended primarily for American readers; but all readers should be grateful for the very clear way in which Brother Potamian has laid out the historical position of Franklin with respect to those contemporaries of his—De Romas, d'Alibard, and Divisch—who have been alleged to have anticipated him with respect either to the kite experiment or the invention of the lightning rod. One amusing reminiscence is recorded in this chapter of the controversy which arose upon knobs *versus* points, and was referred to a committee of the Royal Society. In that committee the Hon. Henry Cavendish and Dr. Benjamin Wilson were opposing partisans. Sir John Pringle, the President of the Royal Society, supported Cavendish in favour of using points. But points had been advocated by Franklin, whom to support at that moment was "unpatriotic." His Majesty George III. accordingly ordered that the points of the lightning conductors at Kew Palace should be replaced by balls; whereupon Sir John Pringle, replying with dignity, "Sire, I cannot reverse the laws and operations of nature," resigned the presidency. This evoked the following witty epigram:—

While you, great George, for knowledge hunt,
And sharp conductors change to blunt,
The nation's out of joint;
Franklin a wiser course pursues,
And all your thunder useless views
By keeping to the point.

The chapters devoted to Galvani and to Volta call for little comment. That on Coulomb gives a better biography than is accessible in English elsewhere. Those on Oersted, Ampère and Ohm are each good in their way; but that on Ohm lacks proportion. One might think that the whole of mathematical physics began and ended with Ohm's "Law."

The lives of Faraday, Clerk Maxwell, and Lord Kelvin are compiled with a knowledge and sympathetic comprehension. The one phrase to which one must take exception in the account of Lord Kelvin is the suggestion—*apropos* of Lord Kelvin's saying at his jubilee that the most strenuous of his efforts for the advancement of science had ended in "failure"—that "because Dame Nature did not open to his

sesame, but persisted in her reticence, the philosopher grew pessimistic and disappointed." "Pessimistic" is the very last adjective to be applied to Lord Kelvin in his cheery and undaunted battling to the last with the deepest problem of mathematical physics. No trace of disappointment soured the serene close of his strenuous life.

There are eight portraits and a score of illustrative cuts in the work, which is well and clearly printed.

OUR BOOK SHELF.

Syllabus of the Lessons on Marine Biology for Fishermen, given at the Marine Laboratory, Piel, Barrow-in-Furness, by the Lancashire and Western Sea-Fisheries Joint Committee. Revised January, 1910. Pp. 35; 7 plates. (Liverpool: C. Tinling and Co., Ltd., 1910.)

This handbook, which has been prepared by Mr. James Johnstone, is written in a clear, direct style, and is illustrated by good text-figures and seven excellent plates. The author is to be especially congratulated on the skill with which he has, throughout the book, avoided the use of technical terms without sacrificing scientific accuracy. The desire to avoid the use of the word protoplasm has, however, led to the use of another term in an unusual sense; on p. 13 the author, dealing with Peridinians, writes:—"They, like the diatoms, are jelly-fish, and have shells" It would be better to avoid the use of the term jelly-fish, in such a connection, in view of its more generally accepted application to organisms of a higher class.

The book contains outlines of lessons on those branches of marine biology which are of special interest to fishermen—the general anatomy, physiology and development of the mussel, the structure of the cockle, the food of these molluscs; the structure of shrimps, crabs and lobsters, their growth, "casting" (ecdysis) and reproduction; the anatomy of the haddock or whiting, the fecundity of various fishes, especially of flat fishes, that of the flounder being studied in detail; the food in the sea, plankton; the different kinds of spawn found on the shore; the elementary chemistry of air and water, the temperature of the sea, &c. This list will serve to show the range of subjects comprised in this admirably planned course of scientific instruction. The book is certain to stimulate the interest, not only of those who attend the classes, but also of other fishermen, to whose notice it will be brought by their more fortunate fellow-workers who have passed through the classes and used the book.

The Sun a Habitable Body like the Earth. By Sree Benoybhusan Raha Dass. Pp. xiv+130. (Naldha: Published by the Author, 1909.) Price 5s., or 3 rupees.

This is, typically, a book "published (and distributed) by the author," and perhaps the kindest statement to make about it is that it is an anachronism. Apparently the author attempts to explain all solar phenomena as electrical effects, and, as a prelude, describes the actions of, and discharges from, insulated conductors; but the language is so often obscure, and, where intelligible, is so devoid of connected reasoning, that no clear idea can be obtained as to the ultimate conclusions. Quotations from great authorities, including Herschel's conclusion as to the sun's habitability, give the volume itself an air of authority which is rudely dispelled on a closer acquaintance.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. No notice is taken of anonymous communications.]

The "Reindeer" from the Lorthet Grotto.

I HAVE just been consulting in *Science Progress* for July, 1909, the very interesting paper of Prof. Sollas on the Palæolithic races, and I venture to direct attention to the title of an illustration on p. 25. It is entitled "Reindeer and Salmon Incised on a Piece of Horn from Lorthet." This legend is taken from the original figure by the late M. Piette in *L'Anthropologie*, 1904, p. 160; but is the Cervus there engraved rightly ascribed to tarandus? Is it not megaceros? Tarandus has no brow tines like those delineated on this horn plaque. They are more or less palmated, while in megaceros they are differently directed, present a different section, and are bifid as are those figured in *Science Progress*. It may or may not be now or later of importance to ascribe correctly this particular drawing, but the determination of the species in prehistoric cave-engravings has an important bearing on the age and climate of the horizon from which they come.

May I venture, if Prof. Sollas will allow me, to refer also to p. 26 of the same important contribution, where occur the words "... Saiga antelope, the same animal as that which is sculptured in so masterly a manner on the spear-thrower mentioned on p. 20 (Fig. 3)." The animal sculptured—also after M. Piette's figure in *L'Anthropologie*—on the implement (from Mas d'Azil) referred to can hardly be a Saiga. The position and form of the nostrils and the uninflated nose-sac which the side-view reveals preclude this determination. The creature must be a goat or a chamois, or belong to a nearly related genus.

HENRY O. FORBES.

The Museums, Liverpool, March 20.

Centre of Gravity of Annual Rainfall.

THE ordinary method of exhibiting the annual distribution of rainfall for any station or country is a graph the ordinates of which represent the monthly rainfall. Though this pictorial method is both useful and interesting, it does not lend itself to the ready comparison of a number of such graphs for different places or for the same place in different years. By a similar graphic method we can exhibit the yearly rainfall totals for a number of years, but we cannot show differences of internal distribution for each year unless we are at the trouble to graph each month of each year separately.

Another method, which may be called the analytical method, I have been applying recently to the study of the rainfall of the province of Mysore, India, upon which I had to report officially from 1893 to 1908, and I have been much surprised at the results brought out by this method. The same method applied to the rainfall statistics of England, Scotland, and Ireland, as given by Dr. H. R. Mill in "British Rainfall" for 1908, shows also curious and interesting results.

The method consists in the application of the well-known formula for finding the position of the centre of gravity of a number of weights placed along a straight rod, viz. $X = \Sigma(wx) \div \Sigma(w)$. If we imagine the rainfall for the months of the year January, February, . . . , December to be weights placed along an axis at distances 1, 2 . . . 12 units from the Origin, or end of the axis (January 1), multiply each month's rainfall by its distance from the Origin, and divide the sum of the products by the total rainfall for the year, we get the position (or date) at which the year's rainfall might be supposed to have fallen all together to give the same effect as the separate monthly falls.

The Mysore Province, which has about the same area as Scotland without the Isles (28,000 square miles), is divided into eight Districts, which differ greatly in the amount of yearly rainfall, as well as in the monthly distribution. Each District is divided into a number of

parishes, called *Taluks*, and the rainfall is gauged at the chief town of each *Taluk*. The mean of these is taken as the rainfall for each District. From the average monthly rainfall of each District for the past thirty-nine years I have found the C.G., also for the year 1908, and they are given for comparison:—

District.	No. of Taluks.	Average for 39 years.		1908.	
		Rainfall.	C.G.	Rainfall.	C.G.
1. Bangalore ...	10	30'48	7'93	25'49	6'47
2. Mysore	13	27'53	7'74	24'24	6'64
3. Hassan	8	37'95	7'62	27'98	6'74
4. Chitaldrug....	9	21'10	7'51	14'03	6'91
5. Tumkur.....	10	25'90	8'01	15'76	7'00
6. Kolar.....	11	27'89	8'14	16'00	7'07
7. Shimoga ...	9	66'60	7'34	67'31	7'14
8. Kadur....	7	73'00	7'40	63'74	7'06

Province ... 77 ... 36'79 ... 7'68 ... 29'94 ... 6'91

The Shimoga and Kadur districts each include three stations where the rainfall is enormously greater than at the other stations; yet though the thirty-nine-years' average annual rainfall for six of the Shimoga *Taluk* stations is only 35·78 inches, and for the three stations of great rainfall it is 128·24 inches, I find that the mean position of the C.G. is 7·28 for these three stations, while for the whole nine stations it is 7·34. In the same Shimoga District there are, besides the nine *Taluk* stations, fourteen additional rain-gauge stations, among which are Agumbi, with a mean yearly rainfall of 333·17 inches, Aralagode, with mean of 237·79 inches, and Karur, with mean of 115·79 inches, and I find the C.G. for these is at 7·29, 7·21, and 7·13 respectively.

It is to be noted that the great deficiency of rainfall throughout Mysore Province as a whole for the year 1908 is indicated, not only by the diminished yearly totals, but by the displacements of the C.G. for each District and for the whole Province. This means, of course, that the deficiency was in the "latter rains"—or those for the north-east monsoon—but the important thing is that we have a simple numerical measure, by combining the displacement of the C.G. and the total rainfall defect, of the real rainfall deficiency for the year. Thus while the rainfall average for the whole Province was 18·6 per cent. less than the yearly normal, the deficiency of the *rain-moment*, as we may call it in the language of mechanics, was 26·8 per cent., which agrees better with the agricultural effect.

This has led me to examine Dr. H. R. Mill's "British Rainfall" for 1908, and the results of working out the C.G. for a large number of stations, and for the 1908 mean rainfall of England, Scotland, and Ireland, are interesting. The position of the C.G. for the monthly mean rainfall of 122 stations in England and Wales is 6·54, of 55 stations in Scotland 6·37, of 53 stations in Ireland 6·72, and of 230 stations in the whole British Isles 6·55. For Greenwich, with rainfall 23·78 inches, it is 6·48; for Borrowdale (Cumberland), with rainfall of 127·38 inches, it is 6·54; for Glenquoich (Inverness), with 107·40 inches, it is 6·21; for Kenmare (Co. Kerry), with 70·91 inches, it is 6·59.

From the Journal of the Scottish Meteorological Society for 1908 I find the following results:—

	Year's Rainfall.	C.G.
Means of the eight principal towns of Scotland	33'05	6'54
Means for all Scotland for 1908	37'55	6'48
Means for all Scotland for fifty years (1856-1905)	39'19	6'87
Means for 1908 of eighteen Lighthouses on the Scottish coast	30'74	6'68

It is remarkable that the rainfall should be so small at the Lighthouses, and that the law of rain-distribution throughout the year should agree with that for the land-stations. The smallest rainfall for 1908 was at the Isle of May Lighthouse, where it was only 18·33 inches, with C.G. at 6·90; and the heaviest rainfall was at Ardnamurchan Lighthouse, where it was 50·99 inches, with C.G. at 6·63.

This method is readily applicable to the graphic presentation for a series of years either of the C.G. or of the

rain-moment. Thus I have worked out the results for Bangalore from 1867 to 1908, and find that while the average position of the C.G. is 7·81, the positions for 1875 and 1876, the successive droughts of which caused the great Mysore famine, were 6·82 and 6·72, and while the average *rain-moment* is 276, it was for those years only 151 and 117 respectively. I also find that for the two years 1907 and 1908 the C.G. for Bangalore was at 6·77 and 6·08 respectively, and that the *rain-moments* were 214 and 157; which agree with the fact that Mysore narrowly escaped another serious famine quite recently, and give a measure of the margin by which it escaped the disaster caused by the rain deficiency of 1875 and 1876.

It is evident that we might easily graph on the same sheet for a sequence of years (1) the total rainfall; (2) its yearly C.G.; and (3) its *rain-moment* or coefficient. This principle will also give the data for charts of the general distribution of rainfall in a country for any year or series of years. That each station and country has its *rain-constant* which can be expressed numerically seems to be more than a mere theoretical curiosity.

Lycopodium Spores.

MISS EDITH A. STONEY states (*NATURE*, January 6, vol. lxxxii., p. 279) that with a large aperture microscope objective and oblique illumination, *Lycopodium* spores are seen to be coated with hair-like projections. We believe this appearance to be illusory. Owing to the transparency of the outermost layer of cells, the margin of the spore is quite invisible under certain conditions, giving to the radial cell walls the appearance of hair-like projections.

Photomicrographs of some of these spores reproduced in the *Physikalische Zeitschrift* of February 1, p. 78, show the effect in question in some parts of the field, and evidence the correctness of the explanation given.

L. W. MCKEEHAN.

Dr. H. J. Hansen and the Copenhagen Museum of Zoology.

I BEG permission to acknowledge the receipt of the open letter sent me through your Journal of March 10, by the leading zoologists of Great Britain and Ireland, regarding my resignation from the Copenhagen Museum and my zoological investigations. I am deeply conscious of the great honour done me in sending me such an address, and I regret that I am unable to write to all personally; but for that reason I would request them through your columns to accept my most sincere and heartfelt thanks.

H. J. HANSEN.
5te Juni Plads No. 1, Kjöbenhavn, F., March 17.

Title of the Natural History Museum.

WHAT has history, in its present sense, to do with the subject? What have the Muses to do with it? Certainly Terpsichore is not included at any of the museums. The N.H.M.(B.M.) is not a museum, but a Natureum. Might not a ten-syllable name on the other side of the way be replaced by the Arteum? Then Bloomsbury might use the name Historeum. The address need not include London or England, as no other place uses these terms. For all scientific reference one word would be complete.

W. M. F. P.

The Meaning of Ionisation.

In his lecture at the Royal Institution on March 11, Dr. Brereton Baker proposed the term *electromerisation* instead of *ionisation* when applied to gases. May I venture to suggest the word "*electronisation*" as more euphonious, and as indicating the essential difference in the process, viz. the freeing of electrons instead of ions?

W. DEANE BUTCHER.

Holyrood, Ealing, March 18.

NUMERALISED PROFILES FOR CLASSIFICATION AND RECOGNITION.

WHEN children or savages attempt to draw a human profile, the result is usually a rude figure that lays stress on five cardinal points. These are the notch between the brow and the nose, the tip of the nose, the notch between the nose and the upper lip, the parting of the lips, and the tip of the chin. Supposing these five points, B' , N' , U' , L' , and C' , to be located with fair precision, as will shortly be shown to be feasible, then Fig. 1 is directly deducible from them, together with the vertical and horizontal axes, $C'B'$, and $C'X$ at right angles to $C'B'$. The position of the five cardinal points varies in different profiles much more than the probable error of measurement. So though Fig. 1 is a mere skeleton, which determines what may be called the set of the features, and corresponds to the primary triangulation of a country, other points are to be derived from it, and similarly utilised. Among these are the intersections with the outline by perpendiculars, drawn from the middle or other specified division of the lines. This skeleton serves as an excellent basis for the classification of profiles and for anthropological statistics.

Peculiarities of profile, as a racial or family characteristic, can be expressed numerically by an extension of this system in a way that promises to be serviceable for eugenic records. It was, in fact, largely with this object in view that I began the

FIG. 1

FIG. 2

FIG. 3

inquiry. The replacement in all scientific work by numerical values, in the place of vague adjectives, is a gain of first-class importance. There is no way known to me, other than this, by which likenesses can be "lexiconised," that is, arranged as words in a dictionary. A needed portrait may by its means be discovered by a formula, as a spoken word is found in a dictionary, by the letters that express its sound. There are many simple purposes of newspaper interest to which this same method might be applied, but with more elaboration.

The practice of cataloguing profiles may perhaps become useful as a secondary means of identification when the number of persons who may require to be identified shall have become too large to be readily dealt with by finger-prints alone.

It will be shown (Fig. 5) that four telegraphic "words" are sufficient to convey a very fair profile likeness. The cost of sending an extra four words by telegram to any part of the British Isles being only twopence, and of a moderate amount over-seas, the practice of telegraphing profiles of persons of current interest, might become common. A refugee criminal could easily be outstripped by his portrait, sufficiently like to him to justify, in connection with corroborative evidence, his being placed for a while under police observation. The measures of profiles must, of course, be reduced to uniformity. Thus, by utilising two out of the five cardinal points to give direction and scale, the mean positions of the remaining three

points may be determined for any given race or family, together with the frequency of deviations of any given amount from those mean positions, and such other deductions as can be reached by the modern methods of statistics.

The corrected values are here described by the same letters as the original ones, but without the dashes. The standard scale that is used is such that BC , the corrected value of $B'C'$, shall be always 50 units in length (see Fig. 5). The reduction is, of course, effected by multiplying each measure in the portrait by 50 divided by its $B'C'$. The number 50 is preferable to 100, which would probably first suggest itself, for a variety of practical reasons, into which I need not now enter. Two figures are assigned to each measure, so the values 0, 1, 2, ..., 9, have to be written 00, 01, 02, ..., 09. The measures are recorded to the nearest integer, there being no room for fractions, decimal or other. A millimetre is a convenient unit for purposes of drawing, more so than one-tenth of an inch; therefore, in reproducing the corrected measures, BC becomes 50 millimetres, and the other measures are altered in the same proportion.

A thick beard interferes with determining L' and U' , but their positions can usually be inferred with a useful degree of precision in moderately bearded faces.

The accuracy with which the five cardinal points can be located differs considerably. The most exact determinations in an unbearded face are those of the points C' and N' , and the direction of the line $C'B'$. U' comes next in order of exactness, then B' , and, lastly, L' . The distance between a line joining $C'N'$ and a parallel line tangential to U' , can be fixed with precision but is not used here. C' and N' are each defined by the intersection of two tangents, as shown for N' in Fig. 3.

It is well to examine these conditions more closely, as they bear on the treatment of curvatures generally. A knowledge of them permits rough and ready drawing, in which the principal matters are attended to, the less essential ones being more or less disregarded. One of the tangents is parallel to $C'B'$, which is treated as vertical; the other is inclined to the vertical at 45° . Consequently, the curve of N' is contained in an obtuse angle of $180^\circ - 45^\circ = 135^\circ$. The tip of each prominence and the bottom of each hollow is represented by one or other of the three short circular arcs shown in Fig. 2, which are sufficiently numerous for the purposes to which they are here applied. The centres of all circles that touch both the vertical and the diagonal will necessarily lie in the line that bisects the obtuse angle between them; consequently, $N'O$ forms an angle with the vertical that is equal to half 135° , or $67\frac{1}{2}^\circ$. The tangent of this angle is 2.4142; therefore the position of the line of centres may be found by laying off a point V in a vertical direction, at 10 units of length from O , and by drawing another line from V horizontally to W , at a distance from it equal to 24.14 of the same units as before. Then the line of centres passes through O and W . It is easily shown (Fig. 3) that the points of contact between the circle and the two tangents are exactly 45° of arc apart. The length of the chord of that angle is equal to about three-quarters of its radius. The shortness of the chord, when the radius is small, is well seen in Fig. 2, and must be borne in mind; it accounts for the scarcely noticeable differences in the curvatures, and consequently for the fewness of the standard arcs that are necessary. The arc of 45° is shown by a heavy line in Fig. 3, where the circle has a radius of 10 mm. There is often a colloquial confusion between the obliquity of the planes between which an edge lies and that of the sides of the edge itself. The former may be very acute, and the angle of the edge would be equally acute if the planes were prolonged until they met; but usually they do not meet, the edge itself being more or less rounded. The acutely inclined faces of a knife may have a blunted edge, that fails to cut the skin without much pressure, while a broken piece of glass, the fracture

of which is perpendicular to its face, but the edge of which is not blunted, only too readily makes a gash.

The arcs of 45° in Fig. 2 all refer to the cutting edge, so to speak. The direction of the lines within which the cutting edge is situated is determined by the adjacent cardinal points towards which they point.

Referring back to Fig. 3, $OP=OM=r$, the radius, $ON=r \times 1.082$, therefore the distance between N and t's circle is only $r \times 0.82$, which for a radius = 10 mm. is about three-quarters of 1 mm. This small value is diminished in proportion for lesser values of r (see Fig. 2), so for practical purposes N (and similarly C) may be considered to lie only just outside the convex circumference of the arc by which they are in each case represented.

The values of r which are used as standards for the lesser curvatures are 2 mm., 6 mm., and 10 mm. The drawings in Fig. 4 are not exactly on this scale, but the differences are unimportant. It is unnecessary to divide these small curves into concave and convex, as their condition in that respect is indicated by the part they play in the profile. Two other curvatures of the larger radii, 25 mm. and 30 mm., are used to express and to define the concavity or the convexity of the ridge of the nose.

It is well, at the risk of some repetition, to describe in a single paragraph the nomenclature of the five cardinal points in the original portrait. B' is the point in the fronto-nasal notch at what is judged to be its deepest part; N' is the tip of the nose, found in the way already described; U' is the point of contact between the naso-labial notch and a tangent, drawn diagonally to it; L' is a point half-way between the furthest positions at which the lips would touch one another if they were lightly closed; C' is found by a similar method to that used for N'.

The portraits are described by numerical formulæ. Each formula consists of four groups of figures, five figures in each group. The shapes of the profile at and immediately adjacent to the cardinal points, and those of the intermediate links, are expressed by single numerals, as set forth in tabular form in Fig. 4. Not more than 0 to 9, or 10, varieties of shape are provided in each case. Thus, the radius of the standard curve that best fits the fronto-nasal notch, b , is expressed by its appropriate numeral, as shown in the first line of Fig. 4; also the inclination of the brow immediately above b , whether it slopes forwards, backwards, or is upright. The ridge of the nose g is counted as either sinuous, concave, or convex, in two or three different degrees, or else as straight. The letter n includes both the very tip of the nose and the outline underneath it, which leads towards the naso-labial notch. The letter u includes the naso-labial notch and the first portion of the upper lip. The lips require two statements, and therefore two separate figures; the former, lp , shows whether the lips are shut, parted in the portrait by 1 or 2 mm., or open by 3 mm. or more, and, again, whether they project evenly, are overhung or underhung. The latter notation, ll , expresses the sizes of the upper and lower lips respectively, whether they are small, medium, or large. The outline between the lower lip and the chin is always notched, and k describes the size and position of the notch, whether it be small, medium, or large, and whether it be high, medium, or low. The curve of the chin itself at C' is not given.

I have called these profiles "numeralised" to express the fact that they are transformed into numerical

formulæ. Twenty figures enter into each formula; they are arranged, as for telegraphy, in the way already described, into four groups of five figures in each group. A "figure," in telegraphic language, includes not only the ten numerals, 0 to 9, but the three symbols in addition, of a stop (.), a hyphen (-), and a short oblique line (/), such as is used in fractions. The arrangement in groups of five, or in "quintets," proved suitable to other similar work on which I was engaged, so it has been adopted throughout. In the four quintets, or, we may say, in the four words that compose a formula, the first three refer respectively to N, U and L, and in that order. The first two and the last two figures, in each of the first three quintets, give the position of the point in question in X and in Y to the nearest whole millimetre. The middle figure of the quintet is derived from Fig. 4 to describe the peculiarities of the profile at and immediately adjacent to that point. The fourth and last of the quintets is preceded by a dot (.), to show that it belongs to a separate category,

FIG. 4.

namely, to the peculiarities of b , g , ll , and k , as set forth in Fig. 4, and in that order. When proceeding to draw a figure from a formula, it is advisable for a beginner to use tracing paper. Then, after drawing an arbitrary line in any convenient place, of 50 millimetres in length, to serve for BC and, therefore, for the vertical axis, and another line CX, at right angles to CB at C, for the horizontal axis, to plot the positions of N, U, and L; then, laying the transparent paper upon Fig. 4, to trace, or copy on an enlarged or reduced form, according to the space available, the figures of n , u , and lp , very faintly. Next to do the same to b , g , ll , and k . Afterwards to harmonise the whole tentatively, with faint and brush-like strokes; lastly, with a free and firm hand to draw the outline through them. Tracing paper may otherwise be convenient, because when the original profile looks to the left, by the simple act of turning the traced outline it affords an almost equally clear profile, looking to the right.

When transforming the portrait into a formula, the reverse process has to be followed with little alteration. Before finally adopting any formula, the portrait should be reconstructed from it and the formula revised where necessary. It is easy after a little practice mentally to compose a formula so far as the seven small letters are concerned, from a brief inspection, either of the picture or of the living face; also to reproduce by copying by eye the symbols from Fig. 4 without caring to trace them. In short, the whole operation may be satisfactorily gone through by an

traits are by no means deficient in resemblance to their originals. I think they are considerably more like to them than the sketches, usually printed in the illustrated newspapers, are to the public characters whom they profess to represent. They are, to say the least, of considerable negative value, sufficing to eliminate at the rate of about nineteen out of every twenty individuals as *not* being the person referred to.

Any form of telegraphy suffices to transmit these four-word profiles. In other respects they are far inferior to those complete pictures now transmitted

FIG. 5.

Explanation of the first formula, namely, that of James Boswell; the others are to be read on the same principle. N_x , 30; N_y , 13. U_x , 28; U_y , 03. L_x , 18; L_y , 03. The small letters are, n , 6; u , 6; l , 4. b , 5; g , 2; h , 2; k , 5.

intelligent person in a rapid and off-hand way. This might become a popular game for the members of a party to practise their art upon one another, care being taken that the five cardinal points should be truly laid down, perhaps by tracing a shadow.

Eight couplets of very different features are given in Fig. 5, both for illustration and for the reader to practise upon. Each couplet contains the original portrait on the left, its formula along the bottom, and the reproduction from the formula (to the standard scale) on the right.

It will be seen from Fig. 5 that four-word por-

traits between certain offices, by means of costly and delicate apparatus, by a method at present not developed to its utmost.

It will be observed that in the second of the portraits, namely, that of Dr. Bennet Langton, the point L lies to the left of CY, and has therefore a negative value. This is -04, but is expressed here as 96, an artifice which practically transfers the horizontal measurement from CY to another vertical line drawn parallel to CY and 100 mm. to its left. No confusion need arise through this transformation, since it leads to very large values lying adjacent to

very small ones, and therefore showing that they belong to a different category. The *minus* values in Y are similarly treated. The process may also be extended beyond the eight squares of 0 to 100 mm. in their sides, that surround the primary one.

My experiments have been chiefly made upon the "Collection of Portraits by George Dance, R.A., Sketched from Life and Engraved in Imitation of the Original Drawings" (Longmans and Co., 1809). They were convenient to work with, being all drawn on scales differing little from that of the standard. All the portraits are unbearded and in exact profile, with three or four exceptions. Those that are available are sixty-eight in number. The name of the person to whom each of the eight portraits in Fig. 5 applies is written along its top, and the volume and page of the two folios by Dance, from which the original was traced, are given in the upper left-hand corners. There are several notabilities in his collection besides those in Fig. 5. Among them are Horace Walpole, General Paoli, Haydn, and John Philip Kemble. An exhibition of Dance's pictures was recently held in London. He had a considerable reputation in his time as a portrait painter.

Methods have been used to aid the recollection of dates and other figures. That by Gray, in his "Memoria Technica," was to transform each numeral into either a consonant or into a vowel or diphthong, as might be the most convenient, and thereby to build up words easy to pronounce and to remember. Those who are familiar with such a process might apply it here, and convert the four quintets of numerals into four words, getting over the difficulty of employing the three additional symbols as best they can. If they succeed, the phrase of "four-word profiles" would be literally exact.

I do not find that a general resemblance can be much increased by using one or a few more quintets or words. A fifth, or even a sixth, quintet might, however, be usefully employed in extending the range of the profile, if it contained one figure to describe the chin and just below it, another to describe the brow, and two figures, 00 to 99, which would perhaps suffice to give the size and general shape of the head, also to define the mustachio and beard of unshaven faces.

The next distinct stage in order of accuracy is separated by a great distance from the present one. It requires so large a number of dots that straight or slightly curved lines drawn through them will flow smoothly when seen at the ordinary reading distance from the eye. It needs as many as perhaps fifty quintets to describe a profile with exactness and the rest of the head with rough precision, and still more to include the eye and ear. I have made many of these, which, when reduced to the standard scale of $BC=50$ mm., are practically identical with the originals, when viewed in a somewhat careless way by a normally sighted person at a distance of 12 inches. A special use is made in this case of the middle figure of the quintet. Thus, the numeral 1 means that a half-unit is to be added to the first two figures; 2, that it is to be added to the last two; and 3, that it is to be added to both of them. This power of doubly minute description is often wanted in the outline that joins and includes the nose-tip and the two lips. Another use for the middle figure of the quintet is to tell that a dotted line should be drawn from the preceding point, to signify doubt of some kind. A hyphen (-) in the middle of the quintet means to begin; an oblique line (/) to end; and a point (.) means an isolated point. But I will not go further into this now; neither will I do more than hint at the way of dealing with portraits that are not in exact profile, by multiplying their horizontal

measures into the secant of the angle through which the profiles are turned away from it.

Much more might be added on extensions of this method, especially as regards its facilities and limitations in conveying plans—ceremonial, strategic, and others—for newspaper use. But its general principles have been explained, and as this article is already too long I will end it abruptly here.

FRANCIS GALTON.

TIDAL OBSERVATIONS IN THE ENGLISH CHANNEL AND NORTH SEA.

FOR the purpose of tracing correctly the progress of the tidal wave throughout its course in the English Channel and North Sea, observations of the vertical movement of the tide at a distance from the land, and similar observations by means of tide gauges on the shore, are equally necessary.

Information on the rise and fall of tide far from the shore may be obtained from a ship or boat at anchor, and in certain localities it may be of considerable value to the navigator.

But, if the observations are carried out with sufficient exactitude to satisfy scientific requirements, the procedure hitherto followed for that purpose necessitates weather conditions which do not often occur, and seldom last long enough for the object in view.

There are other difficulties also to contend with, due to the stream of tide running at its maximum rate at, or about, the times of high and low water. The stream, reversing its direction between those times, causes a mark buoy, or boat, however, tautly moored, to swing over a certain area during the interval; the undulating character of the surface of the ground, and the action of the strong tidal stream on the lead-line, thus tend to introduce elements of uncertainty which increase with the depth of water.

The practical difficulties experienced in obtaining strictly accurate results by this means involve loss of time disproportionate to the value of the observations, and therefore the attempt has not often been made.

Trustworthy evidence on the rise and fall of tide is thus almost entirely confined to the coast-line, with the exception of a few observations of tide-gauges attached to the masts of wrecks on off-lying banks in the North Sea.

A large number of observations of value for the reduction of soundings have, however, been obtained in the North Sea during the years 1886–90 by Captain T. H. Tizard, R.N., C.B., F.R.S., while commanding H.M.S. *Triton* in the course of the survey of the shoals fronting the Norfolk coast. These, being taken by the lead-line from the ship at anchor, on the assumption that the bottom was perfectly level, can scarcely be considered sufficiently trustworthy for scientific purposes until confirmed by more precise methods which were not then available.

More rigorous observations were carried out in the North Sea by the late Captain W. Hewett, R.N., commanding H.M. surveying ship *Fairy* in 1838 and 1840, with the object of verifying the prediction of the late Dr. Whewell as to the existence of an area situated eastward of Orfordness and about midway between the coasts of England and Holland, where the rise and fall of tide was expected to vanish.

The method employed by Captain Hewett was to moor a boat head and stern as tautly as possible by means of lead-lines attached to anchors laid out in the direction of the tidal streams. A remarkable elevation in the form of a ridge on the bottom, with a depth of $18\frac{1}{2}$ fathoms over it, having been previously detected, the boat was moored at slack water as nearly as possible directly over the ridge. Another boat dropping down with the tide, with lead kept just on and

off the bottom, the summit of the ridge was felt with the lead, and the depth over it registered every half-hour from 5.30 a.m. to 8 p.m., August 25, 1840.

The observations, being carried out with the utmost care under exceptionally favourable conditions of weather, gave an absolutely uniform depth throughout the day, showing conclusively that at that spot there was no rise and fall of tide. The position in which the observations were made was in lat. $52^{\circ} 27' 30''$ N., long. $3^{\circ} 11' 30''$ E., the moon's age being 27.6 days, and the maximum strength of the tidal stream 1.6 knots.

The particular spot for observation, as indicated by Dr. Whewell, was about 30 miles S.S.W. (true) from the above position, but circumstances did not permit of reaching it, and no observations have yet been made there.

On a former occasion, on July 5, 1838, the moon's age being 13.4 days, at a position about 20 miles S.S.E. (true) from Dr. Whewell's position, using precisely the same method and under conditions only slightly less favourable, Captain Hewett found a rise and fall of tide of $6\frac{1}{2}$ feet.

The question of tidal observations in deep water having recently engaged attention at the Hydrographic Department of the Admiralty, an apparatus has been devised which obviates to a great extent the difficulties referred to above.

This apparatus, for use from a ship at anchor, is based on a principle similar to that of the pneumatic self-recording tide gauge now under trial by the Admiralty. It consists of india-rubber tubing having a bore of about $\frac{1}{8}$ inch, supplied in a sufficient number of lengths joined together to allow one end open to the sea to be attached to a weight lowered to the bottom near the anchor. The inboard end of the tubing is attached to the upper part of a closed vertical cylinder 4 inches in diameter and about 6 feet high, on the top of which is fitted a small Bourdon gauge of ordinary pattern. The lower part of the vertical cylinder is in connection with an air-reservoir, and is also connected, by a separate pipe of small diameter, with a large Bourdon gauge of special construction.

The air-reservoir, charged by a powerful air pump, consists of four cylinders, each of which is similar in size and pattern to the vertical cylinder. The large Bourdon gauge is 12 inches in diameter, very delicately made, capable of indicating pressures up to 250 lb. on the square inch, and graduated on a reflecting surface to obviate the effect of parallax in reading off. It can be accurately read to within $1/10$ lb.

The method of using the apparatus is as follows:—With the ship lying at anchor, and having sufficient cable veered, the india-rubber tubing should bear no strain. The 12-inch Bourdon gauge being shut off by a needle-valve controlling connection with the remainder of the apparatus, air is pumped into the air-reservoir, flowing from thence to the sea through

tubing and vertical cylinder, controlling connection with the sea, is then closed, and the air reservoir and vertical cylinder charged to a pressure considerably exceeding that of the head of water due to the depth. The compressed air being then admitted to the 12-inch Bourdon gauge by turning the needle-valve, the whole apparatus is again placed in direct communication with the sea by means of the valve for that purpose.

The air pressure as shown by the 12-inch Bourdon gauge will then steadily fall as the air escapes into the sea, and will continue to do so until the pressure in the apparatus exactly balances that due to the column of water represented by the depth over the submerged end of the india-rubber tubing. When the pointer of the 12-inch gauge ceases to fall and remains quite stationary, the gauge is read off.

As a column of sea water 1 foot high, with sectional area of 1 square inch, weighs 0.445 lb., it follows that the depth is obtained by the multiplication of that factor by the pressure in lbs. per square inch as indicated by the gauge. The variation in pressure, provided the weight at the submerged end of the india-rubber tubing has not moved its position, is therefore a measure of the rise and fall of tide.

Observations with this apparatus have been made successfully in depths of 35 fathoms, and the results, when compared with observations of an ordinary tide-gauge on the beach in the immediate vicinity, were found to agree very closely. For purposes of comparison, simultaneous observations were taken afloat and ashore at half-hourly intervals during several days. In fine weather an occasional difference of 2 or 3 inches might be noted, but it seldom exceeded one inch, or even less.

On one occasion when observations were being made during bad weather, force of wind 5 to 6, with the ship rolling and pitching considerably, difficulty was experienced in reading the gauge accurately; the differences observed were consequently somewhat larger, but in no case exceeded 8 inches. The Bourdon gauge used on that occasion has, however, since been vastly improved by the addition of the reflecting surface for the avoidance of parallax, besides other modifications tending towards greater accuracy and facility in reading off. The improved gauge may be expected to give results on which reliance may confidently be placed within a very small margin of error, even under unfavourable conditions.

The apparatus having been thus satisfactorily tested, the officer commanding H.M. surveying ship *Triton* was directed to make observations at certain positions in the English Channel, using the improved Bourdon gauge, with the view of verifying the co-tidal lines as drawn by the late Dr. Whewell from theoretical considerations.

The results given in the following table are very interesting, and show that the theoretical co-tidal lines

All times are G.M. Time.

the vertical cylinder and india-rubber tubing. Pumping is continued until the small Bourdon gauge ceases to rise, thereby showing that all the water is expelled from the tubing, and that the air is escaping freely from the submerged end, at each stroke of the pump. The valve at the junction of the india-rubber

require considerable modification. It may be hoped that with an apparatus available which enables accurate observations to be carried out without unnecessary loss of time, further information may eventually be obtained in many parts of the English Channel and North Sea.

A. M. F.

MODERN AËRONAUTICS.¹

(1) **W**ITHIN about three hundred pages Mr. Turner gives a popular account of the whole field of aërial navigation, including balloons, airships, and aëroplanes, in his survey. He first gives an account of the history and principles of each branch of the subject. In the chapter on the principles of ballooning the expansion of the gas in a balloon appears to be attributed mainly to the heating by the sun's rays, and only a sentence, by the way, refers to the expansion due to the diminished pressure at an increased height, which, of course, affects the gas in the balloon and the surrounding air equally, and also materially affects the vertical stability of the balloon's equilibrium in the air. The natural variation of the temperature of the air with altitude might also be with advantage discussed more fully. In treating of balloons of the non-rigid type, the action of the *ballonet* in preventing flabbiness might be made clearer. On p. 181, after exposing the fallacy of an airship tacking, Mr. Turner seems to say that aëroplanes are on a different footing. Of course, the speed of an aëroplane is relative to the air just as an airship's is, and an aëroplane and an airship capable of travelling at the same speed are under the same conditions as to the directions in which they can travel in a wind. The aëroplane can have the advantage only so far as its speed exceeds the airship's.

The second part of the book deals with various problems which have to be solved. Very interesting speculations are made about the aërial law of the future, and the landmarks, sign-posts, and alighting stations which will be provided for aviators. In chapters on military and naval aëronautics and strategy and aërial invasion, Mr. Turner discusses questions which interest everyone at present. A very clear account is given of the limitations which make some of the achievements that have been attributed to aërial craft impossible, and others improbable of execution, while at the same time full justice is done

¹ (1) "Aërial Navigation of To-day. A Popular Account of the Evolution of Aëronautics." By C. C. Turner. Pp. 327. (London: Seeley and Co., Ltd., 1910.) Price 5s. net.

(2) "Flight Velocity." By Arnold Samuelson. (English edition of "Fluggeschwindigkeit.") Pp. 56; 5 plates. (Hamburg: Boysen and Masch; London: E. and F. N. Spon, Ltd., 1906.)

(3) "The Conquest of the Air, or the Advent of Aërial Navigation." By Prof. A. Lawrence Roth. Pp. x+192; 36 illustrations. (New York: Moffat, Yard and Co., 1909.)

(4) "Aërodynamik: eine Gesamtwerk über das Fliegen." Von F. W. Lanchester; übersetzt von C. und A. Runge. Erster Band. Pp. xiv+360. (Leipzig and Berlin: B. G. Teubner, 1909.) Price 12 marks.

to the great services they can render within their limitations. Mr. Turner's discussion of these important matters can be recommended as sane and reasonable. Other chapters deal with the possibilities of exploration and long-distance travel in general by the air, and in a chapter headed "Work to be Done" attention is directed, among other things, to the need for increased stability in aëroplanes and for a trustworthy light motor.

While those who wish to construct aëroplanes will have to have recourse to fuller and more technical treatises, this book fills a want, and a second edition is already advertised.

In a couple of places characteristically English remarks are made at the expense of mathematicians and men of science in general. These are the more uncalled for in view of the very hazy notions which the book itself shows up, regarding stability and similar questions, that are capable of exact mathematical treatment, as well as experimental tests. The

FIG. 1.—Scouts: old and new. From "Aërial Navigation of To-day."

references to stability alone show a lack of exactness in the use of well-known mathematical and physical terms. Thus in the glossary at the end we have the following definitions:—

"*Equilibrium*.—In flying machines the term is used in the same sense as stability."

"Horizontal stability is the same as longitudinal"; while on p. 291 the author says (of dirigibles):—

"To maintain horizontal stability—that is, to enable the airship to move forward in a straight line without veering to one side or the other—fixed vertical planes at the rear of the frame are used. In addition, there is a fixed vertical plane surface at the rear of the gas-envelope."

The "useful tables" and "glossary" at the end are good features.

(2) Mr. Samuelson's pamphlet, a continuation of a previous publication of the author's, begins with a description and drawings of a model flying machine on the principle of "rowing" flight, and concludes

with a proposal to form a company to construct a full-sized machine from the author's plans. The principles on which the author relies are not those generally accepted. He maintains that the centre of pressure for a plane does not vary with its inclination to the line of flight, that the normal pressure is independent of the inclination, and that flapping wings can be constructed so as to be mechanically more efficient than a screw propeller. To establish these principles he seems to rely on rough experiments with kites and

no writer could possibly bring out a book containing the most up-to-date records in aviation. The author has, on the other hand, brought into prominence several aspects of aerial navigation which are apt to be forgotten in these days, when the breaking of records by 'planes (not to mention other breakages of a regrettable character) is the all-absorbing topic. For example, in chapter i., the ocean of air, we have an account of the results of meteorological observations in which the author has played a most

important part. It is illustrated by diagrams showing the greatest altitudes reached by mountains, balloons, and *ballons sondes*, also variations of temperature and wind velocity with the altitude, and it well shows up the efficiency of kites and *ballons sondes* in exploring regions of the atmosphere to which man can never hope to penetrate. In the second chapter—the history of aërostation—the author reproduces the letters of Benjamin Franklin to Sir Joseph Banks, P.R.S., describing the first balloon ascents made in France. The following extract from one of these letters is worth reading at the present day:—

"I am sorry this Experiment is totally neglected in England, where mechanical Genius is so strong. I wish I could see the same Emulation between the two nations as I see between the two Parties here. Your Philosophy seems to be too bashful. In this country we are not so much afraid of being laughed at. If we do a foolish thing we are the first to laugh at it ourselves, and are almost as much pleased with a *Bon Mot* or *Chanson*, that ridicules well the Disappointment of a Project, as we might have been with its Success. It does not seem to me a good reason to decline prosecuting a new Experiment which apparently increases the power of Man over Matter, till we can see to what Use that Power may be applied. When we have learnt to manage it, we may hope some time or other to find Uses for it, as men have done for Magnetism and Electricity, of which the first Experiments were mere Matters of Amusement."

How true this all sounds to-day! In England there does not, we believe, exist at the present time a single prize for any scientific investigation bearing on aerial navigation. Had such a prize existed the theory of longitudinal and

lateral stability could have been disposed of years ago, and aëroplanes could have been built with a clear understanding of their stability or lack of it. It should surely have been worth while also for those who spend such large sums on construction of dirigibles to take some steps to obtain a theory of their stability, but this has not been done. There are several other problems, including one or two in discontinuous motion, awaiting solution; and it is not the mathematician alone who is handicapped by the persistent refusal of English people to provide any adequate recognition of *original work*.

We should be greatly surprised if members of the engineering profession would not be glad to make use of a similar encouragement to carry out experiments of rather a more scientific character than would

FIG. 2.—Armoured Defence against Airships. From "Aerial Navigation of To-day."

small gliders. The accuracy of the observations and the deductions made from them both seem open to question. Plotting v against t , the graph of

$$v = \frac{I}{\frac{n}{M} + \frac{I}{v_a}}$$

is said to be a straight line, because v and t only appear in the first power. The author maintains that his observations prove Langley's to be inaccurate, and attempts to explain away the discrepancy between his principles and Langley's experiments in a way which is not convincing.

(3) The preface to Mr. Lawrence Rotch's book is dated April, 1909, and when we think of the number of flights performed since then it will be evident that

be otherwise compatible with their business requirements. As it is, there appears to be no such inducement in England for anyone to initiate, undertake, and publish original work, whether on stability, stream lines, propellers, motors, or strength of materials. Indeed, there are very strong inducements for having such work undone, unwritten, and unpublished.¹

The next two chapters deal, respectively, with the dirigible balloon and the flying machine. In the former we have an illustrated historic description, tracing the gradual progress that has been made in dirigibles since the first idea of one was suggested by Franklin in 1784; while in the latter the evolution of the power-driven machine from the mere glider is briefly but sufficiently well discussed. "The Future of Aërial Navigation" is a subject on which anyone with an imaginative mind can write something which people will read with eagerness, and this being the case, we think that Mr. Rotch has been wise in only devoting twenty pages to it, in preserving the historic order, and in giving numerous references to what has been written. The book is, of course, much smaller and less compendious than Mr. Turner's.

(4) That such English people as are able, in spite of their national disabilities, to undertake original work find their efforts appreciated in Germany is well shown by the publication, by the Teubner Press, of a translation of part i. of Mr. Lanchester's book within a comparatively short time of its appearance in England. The English preface is dated October, 1907, the German preface, by Prof. C. Runge, August, 1909, none too long for the work of the translators and printer. We cannot do better now than quote from Prof. C. Runge's German preface in the following terms:—

"The present book contains so many important original ideas and investigations for the development of free flight that German engineers and men of science will be grateful to the publishers for having provided a translation of it.

The author has in some places altered the text, and in others the text has been altered by the translators in consultation with the author, so that the translation may be regarded as a revised edition. A complete retrospect of existing literature was, however, not attempted; this would have altered the character of the whole book and necessitated completely re-writing it, which was not contemplated by the translator.

For men of science the principal charm of the book lies in the ideas on fluid resistance, and the expression of these by exact mathematical formulæ should be the next problem of hydrodynamics."

Does not the last sentence confirm what has been stated above as to the need of prizes for which mathematicians as well as physicists and engineers are eligible?

G. H. BRYAN.

E. H. HARPER.

PROF. K. J. ÅNGSTRÖM.

BY the death of Prof. Knut Johan Ångström, physical science has lost a conscientious and capable worker, in a field which requires long and continuous experience before success can be achieved. For this reason his departure will be felt more severely than that of many men, who perhaps have gained a greater

¹ Mr. Alexander has offered a prize of 1000*l.* to the Aërial League for the best and most trustworthy motor of 20 h.p. capable of running unattended for twenty-four hours. While fully appreciating the importance and value of such prizes, it should be pointed out that the worker who attempts to penetrate more deeply into the thermodynamics or general theory of the internal combustion engine, with the view of paving the way for future improvements, has no prospect of reward, whereas the successful competitor for such a prize may have other prospects of a return for his exertions in the form of patents.

reputation, but have been fortunate enough to interest others in the line of research they have been pursuing.

Knut Ångström bore an honoured name. Those who still remember the early days of spectrum analysis know how much that science owed to the pioneer work of his father, Anders Johan Ångström, whose map of the solar spectrum remained until Rowland's time the standard to which all wave-lengths were referred.

The son was born on January 12, 1857, and received his school and university education at Upsala, where he spent almost his entire life. He was appointed assistant in the physical laboratory of that university in 1882, graduated as Doctor of Philosophy in 1885, and became lecturer in physics in the same year. In 1895 he was appointed to the chair of physics, and at the time of his death occupied the position of pro-rector of the university.

So far back as 1889 we find Knut Ångström investigating absorption phenomena in the infra-red by means of the spectro-bolometer, and during the following two years he obtained valuable results on the absorption spectrum of carbonic oxide, carbonic acid, and marsh gas. He also discovered the similarity in the characteristic absorption of the same substances (ether, benzene, bisulphide of carbon) in their liquid and gaseous states.

We owe to him, further, a valuable investigation on the infra-red absorption of aqueous vapour, carbonic acid and ozone. All these gases are constituents of our atmosphere, and the effect of the two latter on the temperature of the earth may be considerable, not so much because they absorb a certain portion of the solar radiation, but chiefly on account of their much greater comparative influence in preventing the heat radiated from the earth from being dissipated into space. An interesting and instructing controversy took place in connection with the effect of carbonic acid. Arrhenius in 1896 had given a very ingenious explanation of the Glacial period by assuming that the quantity of carbonic acid in the atmosphere had increased since that time. If it be assumed that the absorption is proportional to the total quantity present, it can indeed be shown that a small variation in quantity would exercise a very considerable effect on the temperature; but, as pointed out by Knut Ångström, the proportionality between absorption and quantity only holds when the quantities are sufficiently small, and he showed that the quantity of carbonic acid in the atmosphere must be reduced to about 20 per cent. of its present value before an appreciable effect in the total absorption can take place.

In the course of the further discussion of the subject Ångström carried out important observations on the effect of pressure, and showed that by increasing the pressure, but diminishing the thickness of the layer so that the total quantity of absorbing material remains constant, a marked increase of absorption is noticed at the higher pressure. It follows that in order to find by optical means the quantity of carbonic acid in our atmosphere, it is not sufficient to determine the amount of gas necessary in our atmosphere, it is not sufficient to produce the same absorption as shown by the atmosphere, but account must be taken of the conditions of pressure. Observations on the absorption of ozone also led to the interesting result that there must be considerable quantities of that gas in the upper regions of the atmosphere.

Knut Ångström's name has become more particularly associated with recent researches in the measurement of solar radiation. He constructed an instrument, the essential portions of which consist

of two strips of platinum blackened at the front surface and carrying a thermo-junction at the back. One of these is exposed to the radiation to be measured, while an electric current passes through the other. This electric current is regulated until the two thermo-junctions are at the same temperature. The intensity of the current necessary for this purpose gives a measure of the radiation after certain corrections have been applied. The use of the instrument is simple and convenient, and found so much favour with observers well qualified to judge that the International Union of Solar Research recommended it as a standard for measurement of solar radiation.

Since then the instrument has shown itself liable to certain systematic errors which render further experimental investigations necessary. Its intrinsic merit is, however, so great that it is pretty certain that it will re-establish its reputation, but it is much to be regretted that Prof. Angström's experimental skill is no longer available for the purpose. When the International Union of Solar Research made its recommendation, it was well aware that for a complete determination of the solar constant it is necessary to divide the spectrum into portions sufficiently homogeneous to allow the application of Lambert's law, but such complete determinations need only be carried out in one or two places. Abbot is doing excellent work, and if this be repeated at another station, say in India, the ground will be pretty well covered. In addition to these standards, we require, however, some instrument which is easily transported, and serves to record the radiations received at different times and in different localities.

Angström's pyrheliometer promises to serve that purpose admirably, as soon as more ready means have been found to standardise it easily from time to time, or to obtain a more permanent absorbing surface of the platinum strips. The coloured glasses which Angström recently used to absorb parts of the spectrum chiefly affecting the absorption of aqueous vapour or carbonic acid will probably increase considerably the utility of the instrument.

It remains to notice an important contribution of Angström's in the field of radio-activity. He measured, by means of a Bunsen ice calorimeter, the heat set free in a given time by radium salts, and found it to be constant and independent of the substance in which the radium is placed.

Angström's charming personality endeared him to all with whom he came into contact, and we condole with Swedish science and the University of Upsala in the loss they have sustained. ARTHUR SCHUSTER.

NOTES.

WE notice with great regret the announcement of the death of Prof. Alexander Agassiz, on Monday, at seventy-four years of age.

SIR JAMES DEWAR, F.R.S., has recently received two foreign diplomas, namely, that of Doctor, *honoris causa*, of the University of Brussels, and that of honorary member of the American Chemical Society.

THE Oceanographical Museum at Monaco, established by the Prince of Monaco, was opened on Tuesday by the Prince in the presence of representatives of European Governments and scientific societies. An article upon the museum and the opening ceremony will appear in a later issue of NATURE.

THE third International Physiotherapeutic Congress was opened by President Fallières on Tuesday at the School of Medicine, Paris. A large number of members of the

French Government and of the Diplomatic Corps in Paris, including the British and American Ambassadors, were present at the ceremony.

THE council of the South African Association for the Advancement of Science at a recent meeting resolved by a unanimous vote to offer the presidency of the forthcoming meeting in Cape Town to Dr. T. Muir, C.M.G., F.R.S., and he has accepted the invitation to occupy that office. The actual date of the meeting has not yet been fixed.

LORD KINNAIRD will preside at the dinner to Sir John Murray on Tuesday next, April 5, in connection with the *Michael Sars* expedition for the exploration of North Atlantic waters. The dinner will be held at the Criterion Restaurant, and tickets may be obtained from the honorary secretary of the Atlantic Union, 13A Cockspur Street, S.W.

At a meeting of the National Geographic Society at Washington on March 26, President Taft presented the gold medal of the society to Sir Ernest Shackleton, and in doing so he remarked:—"It is evidence of the society's high appreciation of the marvellous work you have done in the cause of science, of the endurance, courage and intelligence you have shown in the pursuit of a definite object." On March 28 the explorer was presented with the Cullum gold medal of the American Geographical Society, New York.

ON March 23 the Mayor of Doncaster, Councillor Halmshaw, formally opened a municipal museum at Doncaster, for which purpose some of the rooms in a fine mansion, known as Beechfield, have been set apart. These are devoted to specimens illustrating local geology, archæology, and natural history. Mr. T. Sheppard, of Hull, who a short time ago was asked by the Doncaster Corporation to report on the lines the museum should take, was called upon by the Mayor to give an address. In this he dwelt more particularly upon the educational advantages of museums, and the necessity of provincial museums being of local interest. Subsequently the visitors were conducted round the collections, which reflected great credit upon the curator, Dr. Corbett.

ON Tuesday next, April 5, Dr. A. Harden will begin a course of three lectures at the Royal Institution on "The Modern Development of the Problem of Alcoholic Fermentation"; on Thursday, April 7, Dr. T. G. Longstaff will give the first of three lectures on "The Himalayan Region"; and on Saturday, April 9, Mr. W. W. Starmer will commence a course of three lectures on "Bells, Carillons and Chimes" (with musical illustrations). The Friday evening discourse on April 8 will be delivered by Prof. Percival Lowell, on "Lowell Observatory Photographs of the Planets"; on April 15 by Prof. W. J. Pope, on "The Chemical Significance of Crystal Structure"; and on April 22 by Mr. T. Thorne Baker, on "The Telegraphy of Photographs, Wireless and by Wire."

AFTER a number of slight earthquake shocks, an active eruption of Mount Etna commenced on March 23. Signor Ricco, the director of the observatory there, reported in a telegram from Nicolosi, a suburb of Belpasso, that the lava was advancing on March 24 in a stream more than 1500 feet wide, at a rate of upwards of 60 feet an hour. On March 25 he reported that the violence of the eruption had increased notably during the night, and that quantities of scorix were being thrown up, accompanied

by great explosions and rumbling. Five new craters on the south declivity of the mountain, in the same place as those of former eruptions, have been reported. Though on this day the lava stream was larger, it was descending more slowly. The *Times* Rome correspondent reported that on March 27 the activity of the eruption had diminished considerably, and that the lava streams had ceased to flow. The lava appears on this occasion to have flowed farther than in the eruption of 1892. There was renewed activity in the craters on March 28, and a fresh descent of lava, though in more moderate quantities. As yet there is no real anxiety for the safety of Nicolosi or Borello.

THE Reale Istituto Lombardo has awarded the following prizes:—the mathematical prize for an essay on theory of transformation groups is awarded to Prof. Ugo Amaldi, of Modena, for his essay on the determination of all the infinite continuous groups of analytic point transformations in three-dimensional space; the Cagnola prize, relating to miasma and contagion, is awarded to Prof. Aldo Castellani, of the hospital for tropical diseases at Colombo (Ceylon). From the Brambilla foundation for industrial prizes, awards have been made to Elia Bianchi, for his system of constructing dwelling houses formed of hollow concrete blocks, and to Renaldo Rossi, for whole-meal and anti-diabetes bread. The Fossati prize is awarded to Prof. Giuseppe Sterzi, of Padua, for his two published volumes on the central nervous system of vertebrates.

PROF. J. W. H. TRAIL, F.R.S., recently offered to the council of the Linnean Society a sum of money for the purpose of encouraging the study of protoplasm by means of an award to be made periodically. This generous offer has been gratefully accepted, and a special medal has been struck in bronze for presentation with the award, bearing on the obverse a portrait of Linnæus and on the reverse the words "Trail Award" and the name of the recipient in a wreath. It is proposed to make an award about once in every five years for original work bearing directly or indirectly upon the "physical basis of life," and, in accordance with the wishes of the donor, a wide interpretation will be given to the scope of the investigations. The first recipient of the award will be Prof. E. A. Minchin, professor of protozoology in the University of London, whose researches on sponges and protozoa have done so much to advance our knowledge of protoplasmic structures, and who is also the translator of Prof. Bütschli's well-known work on protoplasm.

THE February Bulletin of the Société d'Encouragement pour l'Industrie nationale contains the president's address delivered by M. Bertin at the general meeting in January last; and particulars concerning the award of prizes and medals on the same occasion. We notice that a grand gold medal was awarded to Sir Robert Hadfield, F.R.S. M. L. Baclé, representing the association's committee of chemical arts, points out that Sir Robert Hadfield has at least thirty-one memoirs to his credit extending over the period 1888 to 1909, and that these have been presented to various learned societies in England and America. Among the numerous other awards, we notice that the Lavoisier medal was awarded to M. le Comte de Charbonnet, for the creation of a new industry—that of artificial silks—and that the first award of the recently established Michel Perret medal for scientific workers, who by their researches have contributed to the progress of industrial chemistry, was made to MM. Gall and de Montlaur, for their electrochemical work.

THE New Zealand Survey Department is undertaking, in conjunction with the Marine Department, an inquiry into the tides of New Zealand. Hitherto the tide-tables for New Zealand in the New Zealand "Nautical Almanac" have been supplied by the U.S. Coast and Geodetic Survey; there having been no facilities in New Zealand for the necessary work. We learn from the *New Zealand Times* that the New Zealand Government has been invited by the Secretary of State for the Colonies to supply particulars as to the tides for insertion in the British Admiralty manuals for the use of the Navy and mercantile marine. It is hoped that the results from New Zealand, Australia, and other parts of the Pacific will lead to the thorough investigation of the tides of the Pacific Ocean, of which the available information is at present meagre. The latest scientific apparatus is being obtained from England, and the work has been placed in charge of Mr. C. E. Adams, secretary of the New Zealand Surveyors' Board, and is to be carried on actively at once.

IN the year 1891 Prof. Flinders Petrie found a curious mummy in a plundered tomb (supposed—though there is no positive proof—to have been that of a certain Ranefor or Ranofir) in the neighbourhood of the Medum Pyramid of King Snefru (*circa* 2900 B.C.). The fact that this was the oldest known mummy was duly recognised at the time, not only by its discoverer, but also by Prof. Maspero (see "The Dawn of Civilisation," p. 362), and with due care it was transported to England and lodged in the Museum of the Royal College of Surgeons. The significance of this mummy was not fully realised at the time, because it was generally supposed that the practice of embalming was as old as the history of Egypt, and many museums contained so-called "mummies" almost, if not quite, as ancient; and the importance attached to it seemed to diminish during the following decade, when some archaeologists began describing earlier, even pre-dynastic, "mummies" (see "Guide to the First and Second Egyptian Rooms," British Museum). When, however, it was discovered (see *Cairo Scientific Journal*, May, 1908, p. 205) that there were no genuine mummies in the Cairo Museum (or in the British Museum) earlier than the time of the New Empire (*circa* 1580 B.C.), and that the bodies embalmed in the times of the tenth dynasty (*circa* 2200 B.C.) and twelfth dynasty (*circa* 2000 B.C.), found in 1907 by Mr. Quibell and Messrs. Lythgoe and Mace, respectively, were so fragile that they could not be moved without becoming reduced to mere bones and powder, the importance of the Medum mummy was more than rehabilitated, as was pointed out in *NATURE* in 1908 (vol. lxxviii., p. 342). The age of a mummy such as this was always open to question, seeing that it was found in a plundered tomb; but the important researches carried on by Dr. George A. Reisner at the Giza Pyramids during the last few years have now supplied the data which, when applied to the curious distinctive features of the Medum mummy, fix its age definitely at the period of the fifth dynasty (*circa* 2700 B.C.). Thus the specimen in the Royal College of Surgeons is of the utmost importance to the student of the history of embalming in Egypt, for it is more than 1100 years older than any *actual* mummy exhibited in any other museum, and 500 years older than any other mummy ever found.

MR. C. PEABODY has reprinted from the Putnam anniversary volume a valuable paper on certain quests and doles. He deals first with the rite of Hogmanay practised throughout western Europe, from the Isle of Man to France, in the period extending from late Advent to January. He connects it with a pre-Christian solstitial ceremony prevailing throughout northern and western

Europe. The English Waits fall into the same class. The French *Dimanche des Brandons* is connected by its fire rites with the ancient Pagan ceremonies at the vernal equinox. The paper is remarkable for a very elaborate collection of references to English and Continental folklore.

INFANTILISM and idiocy, and gigantism and idiocy, are the subjects of two papers by Dr. A. Marie in the *Bulletins et Mémoires de la Soc. Anth. de Paris* (5th Sér.), x., pp. 101, 113. He gives a classification of the various forms of dwarfing (nanism and infantilism). He believes that the nanism of the degenerate is nothing else than the permanence of an infantile stage through which all normal persons pass. One may consider the unprofitable age (*l'âge ingrat*) of transition between infancy and the final sprouting of growth at puberty as a kind of transitory normal acromegaly. Gigantism is only the acromegaly of infancy, the unprofitable age prolonged. Giants as well as dwarfs occur in families of degenerates.

THE Touareg, who have been exhibited at Paris, have been investigated by Dr. Atgier (*Bull. et Mém. de la Soc. Anth. de Paris*, 5th Sér., p. 222). The individuals studied were extremely limited in number, and necessarily belonged to the servile classes, as the upper-class Touareg would be too proud to exhibit themselves; consequently they represent a mixed group. On this slender foundation the following results have been arrived at. Excluding the Semitic element (Arabs, Jews, &c.) and the negro element (which is evident in those investigated), one finds the same ethnic groups as those which have peopled Europe—Indo-Europeans or Aryas—that is to say, blonds, brown brachycephals, and brown dolichocephals. Thus the expression "Berber" does not denote a race or variety of the human race, but a conventional term simply signifying those peoples of North Africa who are neither Semitic nor Negroid. According to Dr. Atgier, North Africa, like Europe, has Iberian, Celtic, Basque, and Kymric types, to which the term Aryas of Africa may be applied.

WE have received from the publishers (Bowes and Bowes, Cambridge) a copy of a lecture recently delivered by Mr. W. C. D. Whetham, F.R.S., in Trinity College, entitled "Eugenics and Unemployment." From his book on "The Family and the Nation," the lecturer cites evidence "that, with a few exceptions, the successful families in all classes are voluntarily restricting the number of their children, that their birth-rate has halved since 1876, and that the average number of children to the fertile marriage is now about three. About four children to the fertile marriage is the least number that will maintain a population unchanged. . . . But the population of the country as a whole is still expanding. Hence it follows that the unsuccessful families must still be multiplying rapidly. . . . We . . . are breeding fastest from our less efficient or definitely diseased strains." Having reached this conclusion, the lecturer begs his audience to dismiss any preconceptions and prejudices they may have as to pauperism and unemployment, and to look with him at the facts. He shows a curve based on the annual percentage of the unemployed members of trade unions, but points out that it "is roughly coincident with the cycles of good and bad trade," and "bears very little relation to the curve of general pauperism" or to "the total amount of distress in the country." He shows next how the curve based on the average number of paupers relieved per 1000 of the English and Welsh population has been declining "with natural fluctuations" from 1851 onwards. Since 1900 "there has been a slight increase,

so slight that it is difficult to be sure that it is more than a temporary fluctuation on a curve which shows yearly changes." Despite this warning, Mr. Whetham subsequently suggests that "our failure to go on diminishing pauperism of late years may be due to a slight lowering of the average character and efficiency value of our population," arising from an artificial reduction of birth-rate among "the thrifty, the prudent and the far-seeing, quite as much as by the selfish and pleasure-loving."

EVIDENCE is steadily accumulating to show that most of the forest mammals formerly supposed to be restricted to the west coast of Africa extend eastwards into Uganda. The latest instance of this is afforded by the lemuroid pottos, of which Mr. O. Thomas described an East African species of the genus *Perodicticus* at a recent meeting of the Zoological Society. Sir H. H. Johnston had long since announced the existence of a Uganda potto, but no specimen was forthcoming.

IN No. 4 of the first volume of the *Queensland Naturalist* Mr. G. F. Bennett relates some of his early experiences in hunting and observing monotremes. On one occasion, after digging out the burrow for a distance of about 20 feet, he came upon a nest containing two young duck-bills, probably about a month old, each rolled up into a ball with the tail lying flat on the beak. In other instances the tail covered the head, and the beak rested on the stomach. All young ones of about a month old are plump with a greyish, bare skin.

At the close of an article on the courtship of spiders, contributed by Prof. T. H. Montgomery, jun., to the March number of the *American Naturalist*, it is argued that Dr. Wallace's theory that the generally less conspicuous colour of female birds (as compared with their partners) is due to their need for greater protection will hold good also in the case of the Arachnida. "For the males do not develop their ornamentation until maturity, and they have much less need of protection than the females because they live usually not much longer than a few weeks after maturing, and take no part in the care of the young. The males have fulfilled their main function after impregnating the females, and they are of no use to the species thereafter. But the females live at least several months after maturing, in some cases several years, and they have the whole charge of the eggs and young."

THE March number of *Nature* opens with an obituary, illustrated by a portrait, of Hans Christian Printz, Norway's oldest *savant*, who was born on April 13, 1817, and died, from an attack of influenza, on January 15 of this year in the ninety-third year of his age. On completing his education, Prof. Printz devoted much of his time to botany, and in 1864 made an important collecting tour; but about 1870 his attention was largely directed to meteorology, to which science he devoted much of his time in subsequent years. In addition to this, he was an enthusiastic egg-collector, and at one time possessed between 4000 and 5000 specimens, mainly, it would appear, Scandinavian, among which his greatest treasure was an egg of *Garrulus infans*. About 1871 this collection was acquired by the Bergen Museum.

THE nature and arrangement of the bony armour of the dinosaur *Stegosaurus* are discussed by Dr. R. S. Lull in the March issue of the *American Journal of Science*. In the specimen restored by Marsh a number of small ossicles were found adhering to the under surface of the lower jaw, and these, in the opinion of Dr. Lull, not only formed a gular shield, but also extended over a considerable part

of the body, as it is unreasonable to suppose that any portion of the skin of an armoured reptile would be unprotected. As regards the great vertical dorsal plates and caudal spines, the former of which Marsh regarded as forming a single series, it is practically certain that all were arranged in a double row. The vertical plates are considered to be nothing more than an ultra-development of the longitudinal vertical ridge on the horizontal scute of a crocodile or an unspecialised dinosaur like *Ancylosaurus*. Throughout the back the ribs are T-shaped in section in order to bear the weight of the plates. In the neck the latter are borne on short and notched transverse processes, but in the back these processes become longer and stouter, while in the sacral and anterior caudal region the bases of the plates are approximated and supported on the summits of the tall and expanded neural spines. On the other hand, the terminal third of the tail apparently formed a flexible aggressive weapon, in which the laterally divergent spines were inserted in the muscles between the neural spine and the centrum. Although the caudal spines of the English Kimeridgian *Omosaurus* or *Dacentrus* are structurally identical with those of one of the American species of *Stegosaurus*, in the lack of evidence as to the presence of vertical plates in the former the author is indisposed to admit the generic identity of the Old World and American types.

Dipterocarpus tuberculatus, known locally as the In tree, one of the most important members of the family Dipterocarpaceæ which bulks largely in the Burmese forests, forms the subject of a Forest Pamphlet (No. 13) compiled by Mr. R. S. Troup, and published by the Government of India. As a rule, it is a dominant tree, and an idea of its characteristic gregariousness may be obtained from computations, which estimate fifteen to twenty good-sized trees per acre. Fine specimens attain a height of 90 feet, with a clean bole of 60 feet and a girth of 10 feet. The wood is resinous and heavy, requiring bamboos if it has to be rafted; it is in considerable demand, as it works well, but is not durable if exposed.

A RECENT paper by Prof. G. Klebs, published in the *Sitzungsberichte der Heidelberger Akademie der Wissenschaften* (part v., 1909), and obtainable as a separate brochure, describes the modifications produced in flowers of *Sempervivum* when exposed to special cultural conditions, and incidentally contains some pertinent opinions on the subjects of variation in plants and inherited characters. The species, *S. acuminatum*, chosen for experiment is a recognised natural species. Plants were grown in rich soil and kept at a high temperature. The first inflorescences were cut off when quite young, and dormant inflorescences showing abnormalities were developed, from which self-fertilised seed was collected. Plants raised from the seed were grown, and increased vegetatively for three years. On flowering, the terminal inflorescences were removed as before, and the later flowers produced abnormalities, some new, others similar to those obtained before. These abnormal characters the author recognises as pathological modifications, yet regards their origin as intermediate between fluctuating variations and mutations.

MR. T. PETCH is responsible for three recent Circulars (vol. iv., Nos. 21-3) dealing with fungus diseases, issued from the Royal Botanic Gardens, Ceylon. A bark disease on Hevea and tea that appears during the south-west monsoon is attributed to *Corticium javanicum*. A more insidious disease of Hevea, known as "die-back," is started by a *Gloeosporium* which paves the way for the destructive parasite, assigned to the genus *Lasiodiplodia*. The third pamphlet discusses very fully the

stem-bleeding disease of the cocoa-nut caused by *Thielaviopsis acetica*, a known parasite on sugar-cane in Java. The author communicates a number of details regarding the structure of the cocoa-nut palm. He distinguishes two types of tree, the one with a uniform columnar base, the other with a swollen base, and suggests that the latter, which is the less desirable, has been selected unconsciously by planters.

ACCORDING to the *Agricultural Journal of the Cape of Good Hope*, a certain amount of work on the hybridisation of wheat is being done in Cape Colony. At present less than half the wheat required for consumption is grown, the rest being imported; steps are therefore being taken to increase the area under crop. One of the chief difficulties about wheat-growing in the colony, and particularly in the western provinces, is the vast amount of destruction caused by rust; indeed, this was at one time so serious that farmers almost despaired of making wheat-growing a success. The importation of certain varieties more or less resistant to rust rather relieved matters, but none has yet been found fully to meet the local requirements. A cross between Gluyas and Darling promises to give useful results; Gluyas is resistant to rust but possesses very weak straw; Darling, on the other hand, possesses exceptionally strong straw. A hybrid, Union, has been picked out possessing strong straw and also resistant to rust. Another promising cross is between Gluyas and Du Toits, probably the finest milling wheat in the colony.

IN the *Sitzungsberichte* of the Vienna Academy of Sciences (Bd. cxviii., Heft vii.) P. Vujević discusses at some length the results of five years' temperature observations (1902-6) made at Belgrade. The readings were taken from freely exposed mercury thermometers, with cylindrical bulbs, at the earth's surface and at 0.4, 1.0, and 2.0 m. above it. The results are of special interest in view of the plea for such observations recently put forward in this country. The excess of the mean temperature from hourly readings of the freely exposed thermometer at 2 m. above the mean temperature in the screen at the same height is -0.1° C. in January, $+0.6^{\circ}$ in July. The mean difference is greatest ($+2.0^{\circ}$ C.) at 1 p.m. and least (-1.0° C.) at 8 p.m., in both cases in July. The occurrence of the minimum difference immediately after sunset is attributed to the retention of warm air in the screen. It is probably also due in part to the heat capacity of the screen itself. The point is of importance in connection with the analysis of the daily variation of temperature. Comparisons showed that the freely exposed thermometers gave higher readings at all levels on clear days, and lower readings on a cloudy day, than the aspirated thermometer of the Assmann instrument. The disturbance of the natural condition by the artificial aspiration would have some influence on these results. The observations from the freely exposed instruments are compared with one another without any attempt at correction. Throughout the year the temperature at the earth's surface is lower by night and higher near mid-day than that in the air. The extreme differences between the hourly means for surface and air are approximately $+1.5^{\circ}$, -0.5° C. in January, $+9.1^{\circ}$, -1.6° C. in April, and $+15.2^{\circ}$, -1.0° C. in July. Deposition of dew diminishes the value of the negative difference, while clear weather increases both the positive and negative differences. The temperature on the exposed earth's surface was found to be considerably below that of the neighbouring upper surface of snow. It is assumed that the results are inter-comparable because the thermometers are similar, an assumption which is not justified unless the ventilation is the same for each; this

is probably not the case. No attempt is made to find the effect of varying natural ventilation.

MR. HERMANN GEWECKE sends us a dissertation on the influence of changes of internal structure on the physical properties of copper, electrical conductivity and density being the properties chiefly considered. In this pamphlet of ninety-three pages the author discusses at length the experimental results and theoretical conclusions of previous workers in the same field, and also describes his own measurements of electrical conductivity and determinations of density carried out on a series of copper wires drawn under known conditions. His results show that the effects of wire-drawing depend upon two actions, which occur simultaneously, but to a different relative extent when the circumstances of the drawing process are altered. These two actions are longitudinal extension and lateral compression, and their effects on conductivity and density are opposite in character. The net result is that, as wires become more severely hard-drawn, their density first increases and then decreases again, while the electrical conductivity is reduced—in some cases to an extent exceeding 1.5 per cent. Mr. Gewecke has also studied the annealing process in these wires, but although a temperature of 210° C. is found to mark the beginning of rapid annealing, this temperature is found to vary with the duration of heating. This supports the view of Turner and Levy that the change in the copper is rather of the nature of a continuous re-arrangement of structure than a transformation from one allotropic phase into another, as suggested by Dr. Beilby.

We have before us a draft report of the science standing committee of the Concrete Institute relative to a proposed standard algebraical notation for formulæ and calculations employed with reference to reinforced concrete. It would appear that this was considered last September at Copenhagen by a committee of the International Commission on Reinforced Concrete (established by the International Association for Testing Materials), which approved of a three-alphabet system, the three alphabets employed to be Roman capital letters, Roman small letters, and Greek smalls. The principle of the initial letter is also adopted in the report, though this cannot be made a basis for agreement with Continental nations; it is held, no doubt rightly, that the use of a self-explanatory notation is in this matter more important than international uniformity. The use of Latin smalls for linear dimensions, intensities of forces, &c., and constants, Latin capitals for areas and volumes, and total forces, Greek smalls for angles and constants, is recommended. The notation can be extended by the use of subscript letters: thus B_c may be used for "bending moment at the centre of a beam." The scheme is not put forward as part of a comprehensive system; indeed, it is pointed out that letters fail if any attempt is made at a comprehensive system for engineering formulæ alone, not to speak of physics generally. It is, however, clearly desirable that some general plan should be agreed upon, by engineers at least, before an attempt is made to work out a detailed notation for each branch of engineering work. It may be that the only plan possible is the adoption of some general principles, and those suggested are sufficiently in accord with existing usage. Possibly the Engineering Standards Committee may be able to look into the matter.

A PAPER on compounding and superheating in Horwich locomotives was read at the Institution of Mechanical Engineers on March 7 by Mr. George Hughes, the chief mechanical engineer of the Lancashire and Yorkshire Railway. A number of comparative tests have been made by

the author on compound and simple engines, leading to the conclusion that the compound engine is more economical and efficient than the simple. The compound engine developed a comparatively greater pull on the draw-bar for the same indicated horse-power. The Aintree to Accrington trials show an economy of 23 per cent., and the Goole to Smithy Bridge tests an economy of 22.5 per cent., in favour of the compound, based on the steam consumption per indicated horse-power. On the basis of total steam consumption per hour, the savings in these trials are 39.7 and 33.3 per cent. respectively. In fuel consumption the savings by the compound per indicated horse-power per hour are 16 per cent. and 8.3 per cent. respectively. As the horse-powers developed by the compound are less than for the simple engine, the total fuel savings are 36 per cent. and 23.7 per cent. respectively. Using Schmidt's system of superheating on a six-wheeled coupled goods engine, comparative trials show an economy in coal of 12.93 per cent. per ton-mile for the superheater. Tests on five passenger engines having Schmidt's superheaters, extending over some months, show a coal saving of 21.4 and 21.9 per cent. per ton-mile, computed from the drivers' and guards' returns. Mr. Hughes is to be congratulated on his success in dealing with very difficult problems when applied to locomotives.

An improved form of mouth blow-pipe is submitted for inspection by Messrs. W. and J. George, Ltd., Great Charles Street, Birmingham. It is a burner and air-tube combined, connecting directly with the gas supply by means of rubber tubing, and dispensing with a Bunsen burner. A metal collar at the mouth-piece end keeps the latter clean by preventing it from coming into contact with the bench when laid down. A similar collar at the burner end keeps the flame from scorching the wood. If desired, the instrument can be clamped to a retort stand for use at any convenient height or angle, and it serves instead of a foot blow-pipe for many small operations, such as flame, charcoal, and "bead" tests, and light glass-blowing. The article is neatly and strongly constructed, and for convenience of renewal the several parts are made to a standard size.

THE January number of the *Bulletin de la Société d'Encouragement pour l'Industrie nationale* contains two reports by A. Moreau on two forms of road-tarring apparatus, due to MM. J. Lassailly and J. Vinsonneau respectively. The tar has to be extracted from the barrels, warmed to a temperature sufficient to reduce its viscosity and remove water, and applied to the road as uniformly and as rapidly as possible. In the first apparatus of M. J. Lassailly all these operations are carried out by steam, and require a minimum of skilled control. The Vinsonneau apparatus warms the tar to 80° C. by a thermosiphon heated by a petrol burner, and distributes it by means of compressed air. The cost of superficial tarring by either process is from 8 to 10 centimes per square metre treated.

A SECOND revised edition of the valuable little book on "Butter-making on the Farm," by Mr. C. W. Walker-Tisdale and Mr. T. K. Robinson, has just been issued by the publisher, Mr. J. North, Office of the *Dairy World and British Dairy Farmer*. The original work was favourably reviewed in NATURE of February 12, 1903, and the revised edition should secure for it many new readers. The subject-matter has been brought up-to-date by revision and additions. The price of the book remains 1s. net.

ERRATUM.—March 24, p. 104, col. 1, line 36, for "9 grams" read "6 grams."

OUR ASTRONOMICAL COLUMN.

ASTRONOMICAL OCCURRENCES IN APRIL:—

- April 1. 8h. 29m. Minimum of Algol (β Persei).
 11. Venus, apparent diameter 28'·3".
 16. 16h. om. Saturn in conjunction with the Sun.
 20-21. Epoch of April meteoric shower (Lyrids).
 21. 10h. 10m. Minimum of Algol (β Persei).
 23. 4h. om. Venus at greatest elongation (46° 13' W.).
 25. 5h. 10m. to 7h. 31m. Transit of Jupiter's Satellite III. (Ganymede).
 30. Mercury visible as an evening star situated amongst the Pleiades.

THE SPECTRUM OF COMET 1910A.—In addition to the objective-prism spectra, already mentioned in these columns, MM. Deslandres and Idrac secured some spectra of comet 1910a with a slit-spectroscope of great light-gathering power, which they describe in No. 11 of the *Comptes rendus*.

The series of bands usually ascribed to hydrocarbons and cyanogen, respectively, are fully represented in these spectra, with the exception of the band at λ 460. The hydrocarbon bands of the comet's spectrum exhibit different intensities to the similar bands photographed in the laboratory, with the carbon arc or the Bunsen flame as the light-source, the most refrangible of the blue bands being the most intense. An "unknown" band at λ 402·1 is similar to one which M. Deslandres found in the spectrum of Morehouse's comet, which Prof. Fowler has since traced to some carbon compound at very low pressures, but other "unknown" bands seen in the earlier spectra are not shown in that of comet 1910a.

HALLEY'S COMET IN JAPANESE RECORDS.—Some exceedingly interesting extracts from Japanese records, probably referring to early observations of Halley's comet, are communicated to No. 420 of the *Observatory* (March, p. 129) by Mr. K. Hirayama, of the Tokyo Observatory. They include accounts of comets which appeared in the years A.D. 684, 837, 912, 989, 1066, 1145, and 1222, and generally give some details as to the direction and appearance of the object. The details for the apparition of 1145 are especially full, the observer remarking on the peculiarity that the comet itself should remain bright after the disappearance of its tail; this he explains, four days later, as possibly due to the presence of the moon when the observation was made. The time of perihelion—as calculated by Messrs. Cowell and Crommelin—agrees with the time at which the comet was observed in the year A.D. 912.

METEORIC ASTRONOMY.—Anyone interested in the observations of meteors, and those amateurs who, without the benefit of elaborate equipment, are seeking a field where observations may become both interesting and useful, should read Mr. Denning's article, on the progress of meteoric astronomy, in the current number of *Science Progress* (No. 15, p. 444). The writer therein gives a brief outline of the ideas concerning, and the observations of, meteors, and summarises the chief events in meteoric phenomena since 1798.

The Lyrids, Perseids, and Leonids are especially described, and the association between comets and meteors is concisely discussed. Mr. Denning also mentions that some showers persist, more or less actively, for months, and instances are not wanting where radiants continued in active play all the year round, the apparent position of the radiant remaining practically constant. He also makes it obvious that the study of meteoric phenomena needs recruits; the field is a large one, the observations are comparatively simple, and the results important. So far, photography has played but a small part, and there is ample scope for useful work by those possessing suitable cameras and a fair amount of persistent patience.

STARS WITH VARIABLE RADIAL VELOCITIES.—A number of observations of stars which have been found to exhibit variable radial velocities are published by Messrs. Campbell, Albrecht, and Wright in No. 173 of the *Lick Observatory Bulletins*. Among the twenty northern stars discussed may be noted α Persei, α Ursæ Majoris, ρ Leonis, α , ν , τ and ϵ Draconis, η Lyrae, θ Cygni, θ Cephei, and ζ Capricorni. Six southern stars, observed by the Chile observers,

have also shown a variation of velocity in the line of sight; they are δ Canis Majoris, β Crucis, η Centauri, α Lupi, γ Apodis, and ν Scorpii.

In the same bulletin Dr. Curtis announces that the definitive reductions of the spectrograms of α Centauri confirm the variation of that star's radial velocity. Dr. Campbell notes that thirteen years' observations of Procyon show that the radial velocities do not appear to have varied appreciably in a manner to accord with a period of forty years, more or less; they seem to harmonise with Dr. Auwers's conclusion that the orbit plane of the system is approximately tangent to the celestial sphere. There is, however, a suggestion of a secondary variation of the radial velocity, of very small amplitude and a period of about seven years, for the confirmation of which further observations are necessary.

The minimum of the radial velocity of the binary system in the triple system of Polaris is shown, by the Lick observations, to have been passed, and the velocity of the centre of mass of that system appears to be increasing rapidly. Therefore velocity observations of the bright component of the Polaris system during the next few months promise to have unusual weight in the determination of the period of the third member of the system around the centre of mass of the whole system.

PRECAUTIONS NECESSARY IN PHOTOGRAPHIC PHOTOMETRY.—Under this title Mr. Parkhurst publishes a paper in the *Astrophysical Journal* (vol. xxxi., No. 1, p. 15) which contains a number of hints useful to all workers in astronomical photography.

During the work on photographic photometry, which has been carried on for a number of years at the Yerkes Observatory, it was found that the measures were affected by a number of errors introduced by differences in the method of development, by lack of uniformity in the photographic film, and by many other causes. These errors have now been fully investigated, and the results of the investigations are given in the present paper, illustrated by numerous curves. As an example of the results, it may be noted that at one point of the "developer curves" the density given by "pyro" introduces a difference equal to 0·3 mag. from that given by rodinal, whilst in the case of hydroquinone the resulting difference in magnitude amounts to 0·9. The necessity for rigidly controlling the time of development, the temperature of the developer, and other variables is just as forcibly shown by other curves.

OBSERVATIONS OF SATELLITES.—No. 172 of the *Lick Observatory Bulletin* contains the measures, made by Prof. Aitken during the years 1906-9, of the satellites of Mars, Saturn, and Uranus. In the case of Mars the positions of the satellites are referred to the planet's limb, but for Uranus and Saturn each satellite is referred to another satellite, except in the case of Titania. The positions given in the tables are uncorrected, except for differential refraction.

Photographs of Jupiter's eighth satellite were obtained at Greenwich on January 19 and February 11, and the resulting positions, showing fair agreement with the ephemeris, are published in No. 4393 of the *Astronomische Nachrichten*.

RESEARCHES ON ALLOYS.¹

THE report referred to below was presented to a meeting of the Institution of Mechanical Engineers on January 21. The report itself is a memoir of some 175 pages and sixteen plates, and embodies the results of researches carried out during a period of two and a half years at the National Physical Laboratory. These researches constitute a continuation of the previous work of Messrs. Carpenter and Edwards on the alloys of copper and aluminium as recorded in the eighth report to the Alloys Research Committee. Owing to the magnitude of the task which would have been involved in undertaking a complete study of a ternary system of alloys, the authors at the outset decided to limit their investigations to those regions of the system

¹ Ninth Report to the Alloys Research Committee of the Institution of Mechanical Engineers, by Dr. Walter Rosenhain and Mr. F. C. A. H. Lantberry, on "The Properties of Some Alloys of Copper, Aluminium and Manganese."

where results of practical interest were to be anticipated. As regards the heavy alloys, consisting principally of copper, important results were to be sought only in alloys containing more than 85 per cent. of copper, while at the aluminium end of the series only alloys containing more than 95 per cent. of aluminium could be expected to yield results of practical value. The study of the constitution of the alloys has, however, been pushed beyond these limits in order to render the data obtained over the "useful" range more intelligible.

FIG. 1.—Model of the liquidus surface of ternary alloys of copper with aluminum and manganese.

The report therefore includes a model of the "liquidus surface" of the ternary system over a range of alloys containing less than 11 per cent. of aluminium and less than 10 per cent. of manganese. This model is constructed on the well-known principle of trilinear coordinates, in which the range of compositions of ternary alloys is represented by an equilateral triangle; the liquidus surface is constructed by erecting a vertical ordinate representing the

copper side) are homogeneous, while those to the left are duplex. A comparison of the model with the mechanical properties of the alloys further indicates that in the ternary alloys, just as in the binary copper-aluminium series, the presence of the second phase to the left of the minimum renders the alloys stiffer, stronger, and less ductile.

Throughout the range covered by this model (which represents the data obtained from more than 100 different alloys) no new phase resulting from the presence of manganese can be detected. This result is of special interest, because some of the alloys included in this group, viz. those lying towards the left-hand corner of the model, are distinctly magnetic, their permeability increasing towards the extreme left-hand corner of the figure. If, therefore, the magnetic properties of these alloys (which approach the type of some of the well-known Heussler alloys) are due to the existence of a magnetic metallic compound, this compound must be soluble in either or both the phases found in these alloys.

A photomicrograph typical of the structure of alloys in this region is reproduced from Fig. 75 of the report (Fig. 2), representing the structure of an alloy containing 8.56 per cent. of aluminium, 4.77 per cent. of manganese, and 86.67 per cent. of copper in the sand-cast condition. The effects of heat-treatment on the microstructure of these alloys are very marked. Thus Fig. 122 of the report (Fig. 3) shows the structure of another alloy of this type after annealing at 900° C., both these photographs being taken at the same magnification (150 diameters). Quenching the same alloy from 900° C. produces a totally different structure, reproduced from Fig. 129 of the report (Fig. 4), and this change renders the alloy hard and brittle.

As regards alloys at the light end of the series, the introduction of manganese is found to give rise to the

FIG. 2.—Micro-structure of alloy as cast in sand.

FIG. 3.—Micro-structure of alloy after long annealing at 900° C.

temperature of initial freezing, on the points representing the alloys examined. A photograph of the model, upon which contour lines representing each 10° C. have been drawn, is reproduced in Fig. 1. The well-marked minimum of the copper-aluminium series, occurring at a concentration of about 8½ per cent. aluminium, is continued into the ternary system in the form of a valley in the liquidus surface, and microscopic examination has shown that alloys to the right of this valley (i.e. nearer the

formation of a definite compound, Al_3Mn , which tends to render the alloys hard and brittle. If present in large proportions, this compound appears to undergo a more or less gradual change, which leads to the spontaneous disintegration of the alloys containing it; an ingot consisting of 65 per cent. aluminium and 35 per cent. manganese is a hard, metallic mass when first cooled, but falls to a fine crystalline powder in the course of six or eight hours, and this process appears to be independent of oxidation.

In the "useful" light alloys of the ternary system, however, such disintegration does not occur.

The mechanical properties found in the best of the alloys of the ternary system are remarkable. The authors suggest that alloys of copper with aluminium alone are generally contaminated with a certain proportion of alumina, formed when the aluminium is added to molten copper containing more or less oxygen; by the previous addition of manganese, which acts as a reducing agent, the formation of this alumina is inhibited and the properties of the resulting alloys are improved. It has been found that a small percentage of manganese renders the alloys more ductile without reducing their ultimate strength, while larger proportions of manganese increase the strength but lessen the ductility of the alloys. Sand-castings giving an ultimate strength of 36 tons per sq. inch with an elongation of 22.5 per cent. on 2 inches have been obtained, while in the form of rolled bars the best of the heavy ternary alloys reach an ultimate strength of 43 tons per sq. inch with 22 per cent. elongation. Perhaps the most remarkable result, however, is that obtained with one of these alloys in the hard-drawn condition, where an ultimate strength of 52 tons per sq. inch with 10 per cent. elongation has been obtained. This is probably the strongest alloy known, containing more than 80 per cent. of copper. The remarkable properties of this alloy led Dr. Rosenhain to take up the challenge recently thrown out by Sir Gerard

FIG. 4.—Micro-structure of alloy after quenching from 900° C.

Muntz in his presidential address to the Institute of Metals, to the effect that modern scientific attainments in metallurgy had not yet enabled us to produce a bronze cutting tool. By further cold-working one of these hard-drawn alloys under a powerful testing machine, a material was produced from which a chisel was ground, and with this it was found possible to "incise hard stone or—with a different form of cutting edge—to cut wood so easily and cleanly that a lead-pencil could readily be sharpened with it.

A result of considerable importance has been obtained by means of abrasion tests on certain of these alloys; the test applied was one of simple wear against hardened steel rollers, the loss of weight being determined. It was found that the best of these alloys possess a very great resistance to abrasion of this kind far surpassing even the harder varieties of steel. This property, together with their very great strength and the fact that they can be machined and finished very readily, should render them of special value for the construction of scientific instruments, particularly for those parts where much mechanical wear has to be met. These alloys also possess a very great power of resisting corrosion, both by fresh- and sea-water, while tests made upon them at temperatures up to 500° C. indicate that they retain their strength up to 300° C.; these results suggest the possibility of their employment for the blades of steam-turbines working with superheated steam.

As regards the light alloys, containing more than 95 per

cent. aluminium, the properties of the ternary alloys are not markedly superior to those of the aluminium-copper alloys, except, perhaps, that in the form of chill-castings a higher tensile strength has been obtained. The presence of manganese, however, appears to protect these alloys from corrosion to a marked extent, the specimens of these alloys exposed to sea-water, for instance, becoming coated with a black patina consisting largely of oxide of manganese. Specimens of some of these alloys have retained their original brightness after more than two years' exposure in the laboratory cupboards, thus indicating a decided superiority over pure aluminium, which has hitherto been regarded as decidedly superior to its alloys in regard to corrosion.

ELECTRICAL DISCHARGES OVER PHOTOGRAPHIC PLATES.

IT is well known that when an electric discharge is allowed to take place over a photographic plate a latent image is formed which can be developed in the ordinary way. When one electrode consists of a metal plate placed at the back, and the other is a wire brought into contact with the middle of the sensitive side, a very great difference is obtained when a single spark is passed from an induction coil or Wimshurst machine according as to whether the wire electrode is the positive or the negative one. If it is positive, the figure—which is called a positive figure—consists of numerous ramifications suggesting meandering streams, while if it is negative the main lines in the figure change their directions very abruptly, and are terminated by expansions suggesting fans or palm-leaves. In each case the discharge may or may not pass to the edge of the plate; if it does, the corresponding line is very broad, with a finer, well-defined, intenser line passing midway through it. Such figures were obtained first by Mr. J. Brown, of Belfast, and have since been repeated by many experimentalists. Experiments made by Prof. J. A. McClelland and Mr. Campbell Swinton seem to render certain that the latent image is due to the luminosity of the discharge, and not to a direct electrical action.

I have recently made experiments with the object of extending our knowledge with respect to the formation of these figures, and the results have been communicated to the Röntgen Society, appearing in the society's journal for January.

My first idea was that if the paths of the discharge represent moving electricity they would be seriously modified in a perpendicular magnetic field. However, the greater part of the figure is apparently quite unchanged in such a field; the only evidence of change is in the trunk discharges that flow over the edge of the plate. These become still broader, the fine pilot spark, however, remaining apparently unshifted, and forming a sharp boundary to the trunk discharge along one edge. The direction of lateral shift is that corresponding to a wire carrying a current from the positive to the negative electrode.

A blast of air produces the same kind of effect. Indeed, if several radiating trunk discharges occur on the same plate, the effect in a perpendicular magnetic field is much the same as if a cyclonic blast of air had circulated over the surface of the plate.

The fine tracery lines in the fan-shaped expansions which terminate the lines of discharge in the case of a negative spark are very similar to the paths of the separate portions of an exploded projectile. Such paths are easily plotted by superposing a radial component of velocity, following any assumed law, upon the initial translatory velocity of the unexploded projectile. Owing to this similarity it is suggested that these tracery lines represent the actual paths of single ions or of simple groups of ions in the electrical field.

When the discharge takes place in a partial vacuum very considerable changes occur. In particular, as the exhaustion proceeds a new phenomenon appears, which reaches its most marked stage at about 17 cm. pressure. This is somewhat difficult to describe, and is shown in Fig. 1.

The wire terminal touched the plate nearly at its centre. Besides the trunk discharge ascending the plate are seen

two discharges in the shape of narrow triangles the bases of which are close to a *dark space* separating the glow surrounding them from a central rosette. The pointed ends are close to a *second dark space*, and are terminated by tuft discharges. These appearances show only imperfectly in the reproduction, but are exceedingly definite on the original negatives. The remarkable feature is the very sharp and well-defined edges which these triangles possess. It is suggested that there may be a connection

FIG. 1.—Discharge at a pressure of about 17 cm.

between these and the phenomena of *electrostriction*, but so far no definite theory has been formulated. In very many cases there is visible a *dark continuation* of these squirts on the side of their bases, which suggests that the effects seen represent a part only of the electrical effects taking place. The shape of the squirts suggests that in one region they experience a pressure from the disturbance which creates the luminous glow through which they stretch, and that this pressure is replaced by a tension as soon as the second dark space is passed. The luminous

FIG. 2.—Negative figure in coal-gas at ordinary pressure.

glow bordered by the two dark spaces suggests a single stria as seen in a vacuum tube; the phenomena of ionisation in the two cases may be similar.

When the gas in which the plate is immersed is changed the effects obtained change also. Each gas produces a negative figure characteristic of itself. *The triangular squirts above referred to are given by air alone.* The negative figure in coal-gas at ordinary pressure is shown in Fig. 2. The figure in nitrogen is also very singular.

It is noteworthy that the positive figures in various gases present very few differences from each other.

When a small metallic triangle placed on the sensitive film forms the electrode, some striking differences are obtained according as it is made the positive or the negative terminal. When it is positive the ramifications start in the main from the corners (Fig. 3); on the other hand,

FIG. 3.—Positive ramifications from corners of triangular electrode.

when it is negative a preference is shown to leave at right angles to the edges (Fig. 4).

Throughout these descriptions it has been assumed that the discharges *leave* the electrode. It must be admitted that at present there is no proof that the streamers do not represent currents that advance *toward* the electrodes.

For some further details, as well as for numerous other

FIG. 4.—Negative streamers exhibiting a preference to leave the triangle at right angles to edges.

reproductions, reference must be made to the paper in the Journal of the Röntgen Society from which the figures illustrating this article have been selected. Perhaps it should be added that these are photographic positives from the original photographic negatives.

ALFRED W. PORTER.

FORESTRY.¹

THE present half-yearly issue of the Transactions of the Royal Scottish Arboricultural Society contains a considerable number of useful and interesting articles on forestry and woodcraft generally. An article entitled "The Duty of the State as Regards Afforestation" shows, in a striking summary of the opinions expressed on the subject by landowners, foresters, and men of science, that all are agreed that the State should encourage extended afforestation. The article indicates very clearly what the State can and should do with this object in view.

In "Afforestation and Local Taxation" Sir Kenneth Mackenzie, Bart., president of the society, shows the disastrous results to the local taxpayer which might follow indiscriminate afforestation in large, continuous blocks on land compulsorily purchased by the State. The State could do a great deal to encourage afforestation by private owners by removing the burdens which at present deter many from extending their plantations. In the words of the author:—"There is a premium offered at present against planting—as long as an owner occupies his land with sheep he only pays rates on three-eighths of its valuation. If he fences and plants it, he has to pay rates on the full value appearing in the Valuation Roll."

"The Sitka Spruce as a Tree for Hill Planting and General Afforestation" (with plate), by Mr. Crozier, Durris, is the most important article which has yet appeared regarding the sylvicultural characters and capabilities of this important conifer.

"Vegetable Remains from the Site of the Roman Military Station at Newstead, Melrose," is an article which will appeal to historians and antiquarians. Samples of deposits from the pits and trenches of the Roman station were examined by Mr. H. F. Tagg, of the Royal Botanic Garden, Edinburgh. The numerous twigs and branches examined belonged to some seven different species of trees which have always been considered indigenous. There was no evidence to show the presence in Britain, at the period of the Roman occupation of this station, of species of exceptional interest.

Mr. W. Mackenzie, Forester, Novar, contributes an article entitled "Underplanted Larch Plantations at Novar." The sylvicultural methods adopted to combat the ravages of the larch canker fungus are clearly and succinctly described.

"Continental Notes—Germany," by Mr. B. Ribbentrop, with figures, gives a review of the recent sylvicultural developments in that country, while Mr. A. G. Hobart-Hampden deals in a similar manner with French sylviculture.

The society's excursion to the forests of Bavaria, which took place last August, is interestingly described by Sir Andrew N. Agnew, Bart. In "Notes and Queries" are included many topics of great value to sylviculturists, and the "Reviews and Notices of Books" will bring them in touch with the recent literature on the subject.

WORK OF A LOCAL SCIENTIFIC SOCIETY.

THE value of the work accomplished by local scientific societies is, perhaps, not always given adequate recognition. On what may be described as the educational side, such societies create and foster interest in the world of nature; and out of this comes the desire to investigate parts of the field of science. A report, programme, and presidential address received recently from the North London Natural History Society provide evidence of the well-directed activity and progressive spirit which should be characteristic of a society that desires to extend a knowledge of science, and promote its progress. The society is particularly to be congratulated upon its research committees, which are concerned, among other matters, with the flora, lepidoptera, and birds of the local district. This district covers an area within twenty miles of St. Paul's, and is subdivided into twelve sections for recording.

As instances of the valuable work which these committees accomplish, we mention a few points in the annual report for 1908—that for 1909 not yet being available. It appears that the adventitious flora of the district is spread-

ing widely, while, as might be expected, the native flora is diminishing. Twenty species were recorded for the first time in 1908, making the total of 684 species for the district. Six of these were aliens, and eight were new records for the outlying salt marshes of West Thurrock. Six additions were made to the list of Lepidoptera, bringing the total up to 542. The ornithological research committee, which was inaugurated in 1908, records 110 different species of birds, of which seventy-nine were then known to nest within the district. Two members of the biological research committee, Messrs. L. B. Prout and A. Bacot, have carried out a research on inheritance in *Acidalia virgularia*, and a paper on the results of their investigation was communicated to the Royal Society in February of last year.

It is clear, therefore, that the members are actively engaged in the extension and advancement of scientific knowledge. We congratulate the society upon the keenness and energy of its members and committees, both of which are worthy of emulation by other local scientific societies. The society has just taken rooms in Salisbury House, Finsbury Circus, for its meeting-place, library, and collections. The annual subscription is only five shillings a year, being kept purposely low in order to place the advantages offered within the reach of everyone. It is to be hoped many new and faithful observers will thus be brought within the scientific field through the instrumentality of the society. Subjoined is the main part of the presidential address delivered before the society on January 11 by Mr. Louis B. Prout.

Let us have done with the days of a nearly stationary membership of about seventy, and an average attendance of perhaps a score or less; let us individually use every endeavour to attract to our society all the nature-lovers with whom we come into contact, whether they aspire to be called "naturalists" or not; let us remember that no one who lives within reach of London at all can now plead the inaccessibility of our meeting rooms as an excuse for holding aloof, and that, although our local researches will continue to justify our title of the "North London Natural History Society," yet there is nothing whatever to prevent our drawing upon South London just as extensively as upon North London for our membership. It is proverbial that nothing succeeds like success, and if only the next few months witness anything like the accession of new members which the new facilities make feasible, the future of our society should be well assured.

I have directed attention more than once to the love of facts which has characterised the early career of most of those naturalists who have become the most famous for their theories. The pioneers of evolution—Darwin, Wallace, and Bates—were all careful and accurate recorders at a time when most "mere collectors," at least in entomology, no more thought of labelling every specimen with locality and other details of information than the philatelist of labelling every stamp with the date of purchase and the name of the dealer from whom it was obtained. The two hobbies were very nearly on a par. The collecting was without reservation, an end in itself, and if the entomologist had any advantage over his brother collector, it was only in that he was developing a somewhat more æsthetic taste, and probably—unless he, too, collected solely in auction-rooms and similar localities—a somewhat healthier body. Science and all branches of research were equally beyond the mental horizon of both; and how could it matter when or where a specimen was obtained, unless it might be from the mercenary motive of knowing how to obtain more? I do not say that the outlook of the average collector has radically changed; I do not even say that I wish it radically to change. I have no patience with the lordly being who speaks and writes disparagingly, or even contemptuously, of the "mere collector," and forgets that he only theorises because it amuses him to do so, just as the other only collects with like intent; but I think most have now been educated up to that point where they know that there is value in facts, and I believe that the majority of these are willing to "take themselves seriously" to the extent of observing and recording those facts; and if there are any listening to me who have not

¹ Transactions of the Royal Scottish Arboricultural Society, vol. xxiii., part i. (January, 1910).

yet realised these things, I would urge them from henceforth to bear their part in this movement, which may result in issues more far-reaching than any of us can at the moment conceive. Let me repeat that it is not necessary for every nature-lover, nor for every collector, to become a man of science; yet everyone may become in some measure a contributor to science.

When do the facts observed, or believed to have been observed, become data? Not when they are thrown away loosely into the chambers of memory, to be brought out again for use a few years later, clogged with the dust of time, or metamorphosed by long yet unsuspected contact with some subtle subconsciousness with which they ought to have had no affinity. No; the memory, however excellent, is not a safe repository for facts which are to be used as data; as soon as possible they ought to be reduced to writing. For it is impossible to overestimate the importance of absolute accuracy as a basis for all scientific generalisations.

I have often been impressed with the thought of the dependence of the greatest statisticians on the humblest recorders. Most of us have had questions addressed to us by Prof. Karl Pearson on simple questions of family statistics; and the entomologists have been asked to furnish to the Evolution Committee of the Royal Society certain data regarding percentages of black and of white moths among their favourites. These are but random examples which occur to me of what is constantly going on in the world of to-day; and yet on the faithfulness of the replies to such questions may well hang the entire development of the infant science of eugenics, the whole welfare, and perhaps ultimately the very continuance, of the human race. Fortunately, I believe—and one may hold this belief without a very over-exalted estimate of the average integrity of mankind—the danger of wilful perversion of facts which are to be used as data is extremely small. No doubt there are romancers here and there, and a de Rougemont or a Dr. Cook may set back the clock for a moment or two on occasions; but men such as these have generally some motive of self-interest behind their romancing, and I do not think there is any large army of hoaxers for hoaxing's sake.

Although, however, there is very little to fear from wilful deceivers of their fellows, there is very much to fear from unconscious self-deceivers. It is true that we have little to depend upon, whether in nature-study or in scientific research, but the evidence of our senses; but it is equally true that we must not allow ourselves to be deluded by our senses. I have on other occasions urged that the cardinal virtue of a naturalist is fidelity to his own observations, but he must make very sure that they are observations, and not imaginings. It is a perfectly well-known fact that even careful and experienced men of science have sometimes been led astray by certain psychological processes, and have seen things which it has afterwards been proved to demonstration were not, and could not have been, present for them to see.

The subtle enemy which all observers and recorders have to fight is, I believe, named by psychologists "suggestion," or, more particularly, "auto-suggestion." All of us know, and yet few of us give the knowledge its due weight in dealing with the analysis of our observations, that whatever is present as a mental background is ever liable to colour the newly arriving impressions from without. If something which we see, falls in naturally with our expectations, that is, if its incidence on the mind causes no sense of jarring, we assume that it is correctly observed, and make no attempt at verification; if, on the other hand, it conflicts with our expectation—in other words, with past experiences or general habits of thought—we are sceptical, and demand a repetition of the observation before acknowledging that our senses have not deceived us. Now is there not really a great deal to be said in favour of a diametrically opposite course? Should we not be more suspicious of the expected when it is observed, and more trustful of the unexpected? I need scarcely add that I do not mean this to be the universal principle of life; we should have more than enough to do if, every time we entered our homes, we made it a duty to investigate whether the familiar faces and objects with which we met—and had been expecting to meet—might not in reality be the phantasms of our own brain! I am referring

solely to phenomena which are under observation or investigation for furnishing scientific data; it is in these that we are too apt to accept the expected, perhaps also too apt to discredit the abnormal.

A plain and evident observation, made under no preconceived notion that it was about to be observed, may, in a normal state of health, be noted down as a fact, and thenceforth relied upon. If a member of our ornithological or Lepidoptera committee observes a bird or a moth with which he is well acquainted, he is entitled to make and to use the "record," which should be given full credence. Of course, there may be an error—infallibility is not an over-common attribute of man—and it is always satisfactory if two or three can make the observation simultaneously, or in such a way as to confirm one another, or if, as with our botanical committee, a specimen can be obtained as a voucher; but no good purpose is served by constant suspicion of data of this kind unless the recorder has proved himself untrustworthy. On the other hand, the observer himself should be the first to desire every possible verification, especially in cases of intricacy or difficulty of observation, such as in most microscopic work, or where he has any reason to suspect that "the wish is father to the thought." In all such cases a fact should not be considered as established until it has been verified two or three times, and under the most favourable conditions obtainable.

The most difficult questions of all have been left until last, and I really do not feel competent to give either an adequate answer. What facts or data are worth recording? And what steps should the recorder take to place them at the disposal of the specialist who could use them? In regard to the first question, I would say that, ideally, almost everything is worth recording; but, practically, life is too short, nature too long. While we are staying to record something commonplace, or already well known, we may be missing valuable opportunities of turning our attention to something more important. A retentive memory should be cultivated, so that we may know, to some extent, what has already been established by ourselves or others; and we shall then find that the most casual passing attention will suffice to accumulate any supplementary testimony that may be needed. For the rest, I think we ought to work upon the principle that a few things thoroughly observed and confirmed will form for us a worthier contribution to the sum total of science than a hundred half-observed and half-guessed at. As to the second question. To what use should the recorder put his data? I touched upon this in my former address, but there are great difficulties in the way of the application of sound methods, and the ideal arrangements are as yet far off. A society like ours ought to have a research committee in every possible field of nature-study, besides one or two committees for coordination of work along different lines—organisation, biology, topographical knowledge, bibliography—besides a sort of clearing-house for miscellaneous information; then (and not until then, I fear) it will be possible for observers rightly to place their data, and though much will be handed in which leads no further, there will also be much solid material for the rearing of the noblest edifices in the future of natural-history research.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—The Hebdomadal council has appointed Prof. Poulton, F.R.S., Dr. Dixey, fellow of Wadham College, and Dr. Malcolm Burr, New College, as representatives of the University at the International Congress of Entomology to be held at Brussels in August next.

We learn from *Science* that Columbia University has received an anonymous gift of 70,000l. for the erection of a building for the faculty of philosophy. The University has also received anonymously 3000l. for work in agricultural education. From the same source we gather that a zoological laboratory is to be erected at the University of Pennsylvania, at a cost of about 50,000l. In making the announcement recently, Provost Harrison stated that it would be "the most complete biological laboratory yet

erected." By the will of Mrs. Mary A. Richardson, Tufts College is to receive 800*l.* for fellowships.

By the will of the late Prof. Hilary Bauerman, the sum of 500*l.* is left to the Memorial Fund of the Iron and Steel Institute. The residue of his property (about 15,000*l.*) is left, subject to a life interest, upon trust to be applied by his trustees in the encouragement of the study of mineralogical science at the Royal School of Mines, by means of lectures on subjects of prominent or educational interest at the time, but which are not included in the ordinary list of subjects taught, and for making grants to enable students to make special investigations or to enable them to travel for the better pursuance of their studies.

In addition to the regular courses of instruction given by Profs. Sedgwick and MacBride and by Mr. Dobell at the Royal College of Science, a series of special courses on important departments of zoology are being delivered by lecturers, each as specialist in his particular branch. A course on heredity and variation, by Mr. A. D. Darbishire, has just been completed, and two other courses of great interest will commence shortly. One of these courses will be delivered by Dr. E. J. Allen, director of the Plymouth Marine Biological Station, and will treat of marine biology, with special reference to its bearing on fishery problems as well as on oceanic science. The question of the feasibility of the artificial rearing of marine animals of economic importance will also be dealt with. An opportunity will thus be afforded to the student of obtaining in a condensed form the results of a lifetime devoted to this form of research. The lectures will be delivered on Tuesdays, Wednesdays, and Fridays at 2 p.m., commencing April 19, and will be accompanied by practical work, for the benefit of which salt-water aquaria have been installed in the Royal College of Science, and are now in successful operation; at the conclusion of the course in London the practical part of the course will be continued at the Marine Laboratory, Plymouth, during July, for those desirous of prosecuting the study further. Another of these courses, treating of organs of embryonic and foetal nutrition, is in charge of Mr. Richard Assthen, and will be held on Tuesdays and Thursdays at 5 p.m., beginning on Tuesday, April 19. This course will deal with the comparative anatomy and physiology of the placenta in a comprehensive way, taking into consideration all cases of trophic connection between mother and offspring throughout the Vertebrata, and tracing thus the fully developed placenta of the highest forms from its first beginning. An account of the oestrus cycle will also be given, and the question of the influence of the internal secretions of the generative organs on the organism will also be dealt with. The course will be accompanied by demonstrations and practical work. Such a course has never before been given in London, and it should enable a medical student to grasp the meaning and physiology of the placenta in a way unattainable to those who have only had acquaintance with the human type of the organ.

In an address at the recent annual banquet of the American Chemical Society, Dr. R. C. Maclaurin, president of the Massachusetts Institute of Technology, referred to the necessity for keeping industry in the closest possible touch with science. In the course of his remarks, he said:—"The awful example, the standing warning in this respect, is the case of England. There a few years ago was celebrated the fiftieth anniversary of an English chemist's epoch-making discovery of mauve, and yet the jubilee in honour of this man of science was the occasion of the funeral oration of the colour industry in his own country. This deplorable result was brought about entirely by two things that are closely related:—first, the failure to keep industry in close touch with science, and, second, the impatience of the manufacturer and his narrowness as a self-styled 'practical' man. The practical Englishman is too apt to be impatient of the slow processes of research. He wants to be compensated in hard cash, and at once. The German, on the other hand, has learned to be no less practical, but he has retained the traditions of a race of idealists plodding patiently and surely to success. But the field of industrial chemistry is not the only one in which

the times are critical and exciting. That is equally true of the pure science itself. I hope my own predilection for physics does not mislead me into thinking that the most conspicuous development of chemistry during the past quarter of a century has been on the physical side; but, in any case, there can be no question that the artificial boundaries between physics and chemistry are being rapidly removed, and, of course, it is well to have it frequently brought home to us that all such boundaries are purely artificial. One point suggested by recent experiences is that we should pay more serious attention than we usually do to the logic of science, and have as clear ideas as possible as to what we are really aiming at, as to what we can reasonably expect to do and not to do. It seems unfortunate that men of science are still so much scared by the bogey of metaphysics. What we have to be afraid of is not metaphysics, but bad metaphysics, and it is difficult to accept the simple faith of many a man of science that his metaphysics is to be preferred to any other brand merely because it is either unconscious or naive. A little quiet thought and study should at least have the good effect of enabling us to preserve our calm when things seem to be tumbling down. We should realise, perhaps, that a science like chemistry is, above all else, a work of art, and that concepts like atoms, energy, and the like are not much more than pigments with which we paint our pictures. The next generation may find new pigments or mix the old ones differently."

SOCIETIES AND ACADEMIES.

LONDON.

Geological Society, March 9.—Prof. W. W. Watts, F.R.S., president, in the chair.—E. E. L. Dixon and A. Vaughan: The Carboniferous succession in Gower (Glamorganshire). The succession in three districts in Gower is described. With the description of the lithological sequence are notes on some breccia-like limestones, on "lagoon-phases," and the origin of radiolarian cherts. From the faunal sequence it is concluded that many zones are characterised by the same assemblages as in the Bristol area. The lithological sequence shows (1) that over the area the depth of the Carboniferous sea underwent a cycle of change during Lower Avonian time, the initial deepening being followed by shallowing up to the top of the lower part, C₁, of the Syringothyris zone, deposited almost at sea-level; (2) that a cycle marked the ensuing period up to the top of the Seminula zone; (3) that a cycle took place in the Dibunophyllum zone, the latter reaching the surface; and (4) that a fourth cycle characterised the Posidonomya zone. A comparison of the sequences and thicknesses in the districts shows that the axis on which the movement during the first cycle hinged was different in direction from the axis during the second cycle. The bearing of these movements on the question of the delimitation of the divisions of the Avonian is then discussed. It is suggested that the base of the upper part, C₂, of the Syringothyris zone should form the base of the Upper Avonian. The base of C₂ in at least two localities is connected, faunally, with the zones below, whereas the fauna of the main mass of C₂ passes into S₁ without appreciable change other than the introduction of Lithostrotion. Probably the break between the Lower and the Upper Avonian should be taken at a level within C rather than at the base of the Seminula zone.

Physical Society, March 11.—Prof. H. L. Callendar, F.R.S., president, in the chair.—Dr. W. H. Eccles: Cohers. A method of investigating detectors is developed with special reference to the relations between the energy given to the detector in the form of electrical vibrations and the energy delivered by the detector, as direct current, to the circuit of the indicating instrument. The author puts forward the hypothesis that the properties of an oxide coherer may arise solely from the temperature variations caused in the minute mass of oxide at the contact by the electrical oscillations and by the applied E.M.F. He examines the hypothesis mathematically, and shows that most of the phenomena recorded above can in this way be

accounted for as perfectly as the present state of the measurements permits.—**G. C. Simpson**: Earth-air electric currents. The paper describes a method for recording automatically the electrical current which passes from the earth into the air during periods of fine weather. A large plate (17 metres²) was placed in the open as near to the ground as was consistent with efficient insulation; this was then connected to an insulated vessel, from which water issued through an orifice surrounded by an earth-connected cylinder. The water as it dropped from the insulated vessel carried away, by the well-known "collector" action, all the charge which the exposed plate received, and the latter remained at zero potential. The charged water drops were collected in a vessel connected to a self-registering electrometer, which was earth-connected for an instant at the end of every two minutes. The paper describes the sources of error and the method of determining the value of the earth-air current and of the conductivity of the air from the records of the electrometer.—**Dr. B. D. Steele**: An automatic Toepler pump designed to collect the gas from the apparatus being exhausted.

Zoological Society, March 15.—**Mr. E. T. Newton, F.R.S.**, in the chair.—**T. Goodey**: A contribution to the skeletal anatomy of the fish *Chlamydoselachus anguineus*, Gar. The author dealt with the anatomy of the axial and appendicular skeleton, paying particular attention to the structure of the notochord. He stated that the notochord in this fish had generally been regarded as unstricted except at the extreme anterior extremity, but that he had ascertained the presence of well-developed, calcified cyclo-spondylic centra at the anterior end of the column, and of calcified cyclo-spondylic centra of two sizes in the main caudal region.—**W. R. Ogilvie-Grant**: Additional notes on the birds of Hainan. The notes were based on a small collection of Hainan birds recently forwarded to the Zoological Society by Mr. Robert Douglas, of Shanghai, and, at the suggestion of Dr. Chalmers Mitchell, F.R.S., presented to the Natural History Museum. The collection contained several species of great interest, and two were described as new, namely, *Tephrodornis hainanus* and *Pitta douglasi*. Among the rarities, attention was directed to the remarkable magpie (*Temnurus niger*), with its curious truncate tail-feathers, the beautiful green jay (*Cissa katumatae*), recently described by the Hon. Walter Rothschild, and a bulbul (*Pycnonotus sinensis*), not hitherto recorded from the island.—**Dr. Einar Lönnberg**: The variation of the sea-elephants.

Royal Meteorological Society, March 16.—**Mr. H. Mellish**, president, in the chair.—**Captain H. G. Lyons**: Climatic influences in Egypt and the Sudan. From early times the ancient Greeks recognised the marked difference between the climate of the Mediterranean and that of Africa, and Aristotle indicated correctly the rains of Ethiopia as the cause of the annual flood of the Nile. Travellers have supplemented our knowledge from time to time, but only within the last ten years has a network of meteorological stations given precision to our views and furnished a basis for further investigations. The comparatively low relief of the country, which lies as a vast land area in low latitudes, combined with the effect of the north-easterly trade winds which sweep over it, produce the hot and dry conditions which are so characteristic of north-eastern Africa. Modified somewhat in the north by the warm waters of the Mediterranean, and in the south by the rains of the monsoon in summer, the highest temperatures and most arid conditions are reached between Wadi Halfa and Dongola, where northerly winds, clear skies, and a great range of temperature prevail throughout the year. The important rains are those falling in Uganda, the southern plains of the Sudan, and on the tableland of Abyssinia, since they not only provide the whole supply of the Nile and its tributaries, but largely control their regimen. Fed by the south-easterly air currents blowing in from the Indian Ocean, these monsoon rains supply the equatorial lakes and the tributaries of the Nile; but it is the Abyssinian tableland, with its heavy summer rainfall, which is most effective, since it furnishes the whole of the Nile flood and enables the Nile to maintain itself

through 1500 miles of desert. As the sole source of the flood, the variation of these rains directly determines the abundance or deficiency of Egypt's supply, so that this climatic problem is of immense importance. Hardly less important in these days of intensive cultivation of cotton is the study of the winter storms which occasionally break in the Sudan and Abyssinia, raising the level of the rivers and increasing the supply of the Nile appreciably at a time when the normal supply is inadequate. The climate of the region not only influences the water supply, but the great range of temperature rapidly disintegrates the rocks, and the wind removes the finer portion of the material. In this way the deserts are being constantly modified, and vast ranges of sand dunes are piled up. The distribution of vegetation is very markedly influenced both by the moisture and by the physical character of the country.

Linnean Society, March 17.—**Dr. D. H. Scott, F.R.S.**, president, in the chair.—**E. P. Stebbing**: The life-history of *Chermes himalayensis* on the spruce (*Picea Morinda*) and silver fir (*Abies Webbiana*) of the N.W. Himalaya. The life-histories of the European species of *Chermes*, *C. abietis* and *C. viridis*, have been studied by Blochmann and L. Dreyfus in Germany, Cholodkovsky in Russia, and more recently by E. R. Burdon, of Cambridge. It is now well known that *C. viridis* has alternating series of generations upon the spruce and larch. The discovery that a species of *Chermes* formed galls on the spruce in the Himalaya was first reported by A. Smythies, of the Indian Foreign Service, in 1892. These were considered by the late Mr. Buckton to be *Chermes abietis*. Investigations commenced by the author in May, 1901, and carried on intermittently up to July, 1909, have led to the discovery that this *Chermes*, although an undescribed species, has a life-history somewhat similar to the European species of the genus, having series of agamic generations alternating between the spruce and silver fir (which grow together in mixture in the western Himalaya), with a sexual generation occurring but once a year, in the autumn, on the spruce. The paper shows that the Himalayan insect passes through similar generations to its European congeners, to which the names *Fundatrices*, *Alatae*, *Colonici*, *Sexuparae*, and *Sexuales* have already been given by European investigators. The periods at which these generations are to be found upon the trees in the Himalaya differ considerably, however, from the European ones, and are apparently chiefly governed by the appearance of the monsoon early in July in this region.—**R. S. Bagnall**: A contribution towards our knowledge of the neotropical Thysanoptera.

Institution of Mining and Metallurgy, March 17.—**Mr. Edgar Taylor**, president, in the chair.—**W. A. MacLeod**: The surface condenser in mining power plant. The author conducted a number of tests on the winding engines of a mine with which he was connected, the results of which were embodied in this paper, together with a vast amount of other information concerning the relative consumptions and efficiencies of condensing and non-condensing engines. He found that the employment of condensers was distinctly beneficial in both respects, even under the intermittent conditions attaching to most mining power plants, and the results of his investigations have enabled him to determine with some exactness the leading features to be emphasised in the laying down of a condensing plant suitable for work of a more or less intermittent nature, as in the case of winding engines.

CAMBRIDGE.

Philosophical Society, February 21.—**Prof. Seward**, vice-president, in the chair.—**Prof. Punnett**: Mimicry in Ceylon Rhopalocera, with some notes on the enemies of butterflies.—**A. R. Brown**: The Andaman Islands. Some of the features of the physical anthropology and the social life of the aborigines of the Andaman Islands were briefly described. The extremely primitive characteristics of the Andamanese are to be attributed to their long isolation from all other races and peoples, and the stability of population.—**T. G. Edwards**: The procession and pupation of the

larva of *Cnethocampa pinivora*. The processionary habits of the larva of this moth—which is abundant in the pine woods of the neighbourhood of Bordeaux—were first studied by Réaumur in 1736, and again by Fabre in the latter half of the last century. Both these writers describe the life-history and habits of the insect in considerable detail. The present paper, which is a summary of observations made during a fortnight spent at Arcachon, is an attempt to supplement these accounts by supplying information on certain points which still remain obscure. The procession is one of single file, the whole moving along a silken thread which is commenced by the leader and added to by all the larvæ in succession. The author found that though any larva could function as leader, yet the leader was capable of taking a real initiative in cases, such as the selection of a path, burrowing for pupation, &c., the satellites following him whether influenced by the same stimuli or not. The "circulating mass" is a formation which the larvæ frequently adopt when on the march. It consists in an assemblage of larvæ moving among each other, the mass, as a whole, remaining stationary. A "circulating mass" is always formed before the larvæ burrow for pupation. The leader appears to start the process of formation by assuming a zig-zag mode of progression, which is followed by the satellites. Though the order is completely broken up within the mass, yet it was found in every case observed that the leader of the procession which was re-formed from it was identical with that of the original procession. This was ascertained by marking the larvæ by means of fine sand or flour scattered over the dorsal papillæ. Pupation occurs beneath the ground, and is complete about nineteen days after burrowing. The burrowing is a collective process, in which all the larvæ within a circulating mass take part.—Prof. W. Burnside: Double sixes.—H. Bateman: The solution of a system of differential equations occurring in the theory of radio-active transformations.—Dr. Young: The change of order of integration in an improper repeated integral.—R. T. Beatty: The production of kathode particles by homogeneous Röntgen radiations. The kathode particles produced when these radiations pass through a thin silver leaf are absorbed by air, so that their coefficient of absorption is a linear function of the coefficient of absorption in aluminium of the exciting radiations. The total energy of the kathode particles set free in the leaf is proportional to the absorption by the leaf of the radiations. The range of these particles in hydrogen relative to that in air increases with the speed of the particles from 5 to 8. The total ionisation produced by any bundle of these kathode particles when totally absorbed in hydrogen is the same when air replaces hydrogen.—Sir J. J. Thomson: The scattering of rapidly moving electrified particles by matter, and its application to the determination of the number of corpuscles in the atoms of the various elements. An expression for the scattering of a pencil of rapidly moving electrified particles is found by the following method. First calculate the average deflection of the direction of motion of an electrified particle when passing through an atom which is assumed to consist of a large number of corpuscles placed in a sphere of uniform positive electrification; the expectation of any angular deflection after a large number of particles have passed through a large number of atoms can then be found by the theory of probability. In this way it is shown that the average angular deflection when a pencil of rapidly moving particles passes through a thin plate of thickness t is

$$\frac{e^2}{mv^2} \sqrt{\pi N_0 \left(64 N_0 + \frac{\pi^2}{16} N_0^2 \right) t},$$

where v is the velocity of the particle, e the charge, and m the mass of the particle, N the number of atoms in unit volume of the plate, and N_0 the number of corpuscles in each atom in the plate; hence if we measure the scattering of such a pencil we can determine the value of N_0 .

MANCHESTER.

Literary and Philosophical Society, February 22.—Mr. Francis Jones, president, in the chair.—A. Brothers: Halley's comet as seen in 1835, compared with Donati's in 1858. Good drawings or sketches of Halley's comet

seem to be rare. Sir John Herschel saw the comet at the Cape of Good Hope, and from his sketches it was not very conspicuous. Struve in 1835 gives a sketch which shows it to have been bright, probably when it was near the sun, but as a brilliant object it must have been very inferior to several which were seen during the nineteenth century. The author has a distinct recollection of seeing the comet in 1835. The object certainly was not so bright as Struve shows it to have been, and still greatly inferior to Donati's comet. It is generally spoken of now as likely to appear as a brilliant object, but the author points out that there is little evidence for the assertion.—Dr. H. F. Coward: The inflammability of gas-mixtures. Hydrogen and oxygen mixtures were shown to be capable of inflammation at a much lower pressure than had been imagined previously if the igniting spark were produced in the most suitable manner. Minima for sparks of various nature with electrodes of various kinds were given.

March 8.—Mr. Francis Jones, president, in the chair.—D. M. S. Watson: Upper Liassic Reptilia, part ii., the Sauropterygia of the Whitby Museum. The chief Plesiosaur in the Whitby Museum is the type-specimen of *Plesiosaurus propinquus*, Blake. This is re-described in the present paper. It is a member of the large-headed group of Plesiosaurs, but differs considerably from other Liassic species, such as "*Thaumatosauros*" *megacephalus* (Stutchbury) and *Rhomaleosauros cramptoni* (Baily and Carte). It may possibly be necessary to found a new genus for the species. The other remains consist of small groups of vertebræ, one set of which, containing fifteen cervicals of *Sthenarosauros dawkinsi* (Watson), may be Owen's type-specimen of *Plesiosaurus coelospondylus*.—Sir W. H. Bailey: Mr. Myring's recent discoveries of prehistoric pottery in Peru. Mr. Hewitt Myring, a mineralogist and mine owner, visited the Chincuna Valley in Peru, and explored some sand ridges with the view of finding something in the Inca graves. The valley, however, had been used as a cemetery, not by the Incas, but by the Chimus, who preceded them in the occupation of the country, and the work of exploration brought to light several hundred pieces of pottery of great variety and interest. The pieces are well preserved, owing to the absence of rain and the consequent dryness of the soil. This pottery, some of which recalls that of China, India, and Egypt, shows great care, skill, and art, especially in the modelling of the human face, and is remarkable in that no two pieces are alike, a fact which demonstrates, the author thinks, the intellectual liberty and original genius of these early craftsmen. The age of the pottery is not known, and may be several thousand years. About one-third of the pieces discovered have been secured for the British Museum, and it is hoped that shortly some portion of the collection may find a permanent home in Manchester.

EDINBURGH.

Royal Society, February 7.—Dr. J. Burgess, vice-president, in the chair.—Prof. Cossar Ewart: The short-tailed domestic sheep.—Principal Laurie: Electromotive force of cells with a single salt and two solvents. The paper gave some preliminary results with cells in which potassium iodide was the salt and water and alcohol the solvents, as, for example, the relation of the electromotive force to the strengths of the solutions, the variation with temperature, and the connected thermal properties, &c. In co-ordinating the curious results obtained, the author brought forward some suggestive views as to the distribution of molecular energy in the two solutions.—Prof. F. G. Baily: A stereoscopic optical illusion. When two objects are nearly in the line of vision, so that when one is clearly focussed the other appears as two images, one on each side of it, this clearly focussed object appears to be, under certain conditions, distinctly nearer to the observer than it really is. The phenomenon was noticed accidentally, and a careful study showed that it occurred only for a certain range of distances. It was evidently a physiological effect.—Drs. E. P. Cathcart, J. Gray, and A. Black: A new form of respiratory calorimeter for physiological purposes. The temperature of the entering and issuing air was measured by platinum thermometers or thermoelectric junctions, the whole being under perfect automatic control,

so that the exact amount of heat generated within the calorimeter could be estimated.—**Dr. T. Muir**: The theory of perysymmetric determinants in the historic order of development up to 1860, and the theory of bigradiants in the historical order of development up to 1860.

February 21.—**Dr. Traquair, F.R.S.**, vice-president, in the chair.—**J. Murray**: Scientific work of the British Antarctic Expedition of 1907-9. Moraines were traced on the sides of Mount Erebus to a height of 1100 feet. At the same time, there are abundant evidences of recent elevation of the land to the extent of several hundred feet, so that it cannot be said that glaciers ever stood so high as the moraines now stand. The tabular Antarctic icebergs appear to consist of compressed snow, not ice. They float very high, the depth of the substance below water being just about equal to the height above. By the fortunate re-discovery of a dépôt laid down by Captain Scott on known bearings six years previously, the average rate of travel of the Great Ice Barrier at its western edge was found to be, on the average, about 500 yards per annum. The accumulation of drift on the Barrier surface was measured at the same place, and averaged just above 1 foot per annum of compressed snow. With these somewhat rough data as basis, it was estimated that the snow cliff, which to a height of 200 feet forms the face of the stratum at sea-level, must have originated some fifty miles to the south some 200 years ago. Yet under this long-continued weight of accumulated snow the material is not transformed into ice. The original glacier ice depressed beneath the accumulating snow seems to have been corroded away below sea-level, as the whole barrier moved outwards from the land valleys. Some important conclusions may be expected to result from a study of the rocks collected, especially if the discovery of coal and fossil wood should lead to the determination of their geological horizon. Of the optical phenomena observed, one of the most interesting was the projection, as long tapering dark bars through the air, of the shadows of mountain peaks. Under certain conditions the observer saw the shadow of Erebus cast on to Mount Lister, appearing as a circular arc reaching a height of 30° or more above the horizon. The observer was looking transversely to the direction of the shadow. Aurora displays were very frequent. They seemed to be dominated by the mass of Ross Island, and frequently circled Mount Erebus. The chief fact of biological interest was the abundant development of microscopic fauna and flora in the shallow lakes. The micro-fauna survives from year to year frozen in the ice without suffering injury. The lakes attain a temperature as high as 60° F. in summer, and in winter may go down to -40°. In some deeper lakes, which do not thaw in ordinary summers, many live animals were found at the bottom under 15 feet of ice. These must have been frozen for years. It was shown by experiments that they can endure being heated when in the dry condition almost to the boiling point and cooled to -108° F., a range of 300°. As regards the vital phenomena exhibited, there was a striking contrast between the fresh-water animals and those living in the sea not many yards away. These perform all their vital functions several degrees below the freezing point of fresh water, and are killed if the temperature either rises or falls one or two degrees. The rotifer fauna of the Antarctic lakes, which alone has been fully worked up, is very limited in numbers, and presents distinct peculiarities. Of the sixteen species recognised, five are at present unknown elsewhere, and many of the others differ from the usual types. These facts point to long isolation and difficulty of access to the region.

DUBLIN.

Royal Irish Academy, February 28.—**Dr. F. A. Tarleton**, president, in the chair.—**J. J. Simpson**: A revision of the Juncellid group of the Gorgonellidæ. According to the author, the Juncellid group of the family of flexible corals (Gorgonellidæ) comprises the genera *Juncella*, *Ellisella*, *Scirpearia*, *Scirpearella*, *Ctenocella*, and *Nicella*. Having had special facilities for studying these forms in the living condition when taking part in some of the cruises of the Indian Government steamer *Investigator*, the author has been able to add a good deal to the knowledge of their

mode of life, structure, and distribution of which in some cases our information was very deficient. He directs special attention to the great taxonomic importance of the canal system and the character and variety in type of the minute spicules. A full description of the family Gorgonellidæ and its genera, with new diagnoses, conclude this contribution to our knowledge of the flexible corals.—**J. Adams** and **G. H. Pethybridge**: A census catalogue of Irish fungi. This paper contains an historical account of the previous work which has been done on the Irish fungi and Myxomycetes from the first published records in 1726 up to the present day, together with a complete bibliography of the subject. It also contains a complete list of all the fungi hitherto recorded as occurring in Ireland, together with a few hitherto unrecorded species. The arrangement follows that adopted in Engler and Prantl's "Pflanzenfamilien" in the main, and the distribution of each species in the four main provinces and in twelve sub-provinces is indicated. The total number of species, including Myxomycetes, recorded is 1464, which probably represents far from the actual number of species occurring in Ireland, seeing that the province of Connaught is at present almost virgin ground so far as these plants are concerned.—**J. Adams**: A list of synonyms of Irish algae, with some additional records and observations. The greater part of the paper consists of a list of the names under which Irish species of algae were originally published, and of the modern names of the species to which they are considered to be equivalent either in whole or in part. Some additional records have been brought together, numbering rather more than a hundred species. There is a revised census of species, a list of errata occurring in the "Synopsis of Irish Algae" published in 1908, and some additional bibliographical records.

PARIS.

Academy of Sciences, March 21.—**M. Émile Picard** in the chair.—**M. Metchnikoff**: Experiments in typhoid fever. Hitherto it has been impossible to make satisfactory experiments with this disease on animals owing to the invariable fatality, but by making the attempt of inoculating a chimpanzee with typhoid matter from infected excreta, many interesting observations have been obtained, which are described.—**J. Guillaume**: Observations made on the sun at the Lyons Observatory during 1909.—**A. Chatelet**: A transformation of continuous arithmetic fractions.—**A. Cotton** and **H. Mouton**: The magnetic and electric bi-refractivity of aromatic liquids and the theory of molecular orientation.—**Ch. Maurain**: Variation with temperature of the magnetic properties of iron in a weak magnetic field.—**M. Robin**: The phenomenon of the extinction of sound in iron.—**Jean Meunier**: The laws of combustion.—**J. Ville** and **W. Mestrezat**: The hydro-fluoric hydrolysis of cellulose.—**L. Blaringhem**: An unstable variety of *Nigella*, *Nigella damascena cristata*, obtained after a mutilation.—**L. Moreau** and **E. Vinet**: The use of lead arsenate in vine culture. Among other observations, it was definitely shown that the lead arsenate did not make its appearance subsequently in the wine.—**Maurice Holderer**: The filtration of diastases.—**M. Doyon**: The normal secretion in the liver of a substance preventing coagulation of the blood.—**Jean Giaja**: The isolation of a biase sugar derived from amygdalin.—**MM. Lagriffone** and **Roger**: Malta fever in France.—**L. Lindet**: The raising of flour in baking.—**Ph. Glangaud**: The architecture of the central part of the Monts du Forez.—**Marcellin Boule**: Some vertebral fossils from the district south of Tunis.—**M. Nouailhac-Pioch** and **Edmond Maillet**: The rise of the Seine in January-February, 1910.—**B. Galitzine**: The determination of the epicentre of an earth tremor, from the data provided by one seismic station.

CALCUTTA.

Asiatic Society of Bengal, March 2.—**I. H. Burkill**: Notes on the pollination of flowers in India, note No. 7. A few observations made in the Central Provinces and Berar. The notes were made in the Central Provinces and Berar, chiefly in the Melghat. In the Melghat at the end of the rains, flower-visiting

insects are rare. *Megachile albifrons* was observed to be a regular visitor to cotton-flowers in north-eastern Buldana. As cotton has been asserted to be self-pollinated constantly in western India, and as some of the agricultural departments have been endeavouring to improve the plant on the assumption that races ought consequently to continue pure though grown by the side of other races, the observation has interest in directing attention to the necessity of relying on artificial pollination in breeding experiments. *Apis dorsata* was observed to work in the dawn and dusk on the flowers of *Dalbergia Sissoo* at Nagpur.—I. H. Burkill: Note on the spreading of *Croton sparsiflorus*, Morung, along the Assam-Bengal Railway. This introduced plant has reached Lumding and Gauhati by means of the Assam-Bengal Railway, along which it is to be found in several places between them and Chittagong. Chittagong is the port whereby, doubtless, it entered India.

GÖTTINGEN.

Royal Society of Sciences.—The *Nachrichten* (physico-mathematical section), part iv. for 1909, contains the following memoirs communicated to the society:—

July 3.—G. Angenheister: Cloud observations in Samoa.

November 20.—Rudolf H. Weber: Asymmetric and symmetric tensors.—The late K. Zoeppritz and L. Geiger: Seismic waves, iii., calculation of path and velocity of precursive waves; Poisson's constant in the interior of the earth.

December 4.—Researches from the Göttingen University chemical laboratory, xxii. Remarks on the terpinene question.

The "Business Communications," part ii. for 1909, include the text of the address presented to the University of Cambridge at the Darwin centenary, and a discourse by G. Berthold on organisation, morphogenesis, and metamorphosis in plants.

DIARY OF SOCIETIES.

FRIDAY, APRIL 1.

GEOLOGISTS' ASSOCIATION, at 8.—An Account of the District to be Visited at Whitsuntide (the Isle of Purbeck and Bournemouth): H. W. Monckton and F. Hovenden.

MONDAY, APRIL 4.

SOCIETY OF ENGINEERS, at 7.30.—Moulmein Waterworks: P. G. Scott.

ARISTOTELIAN SOCIETY, at 8.—Bergson's Theory of Instinct: H. Wildon Carr.

SOCIETY OF CHEMICAL INDUSTRY, at 8.—The India Rubber Industry: Dr. P. Schidrowitz.

VICTORIA INSTITUTE, at 4.30.—Darwinism and Malthus: Rev. J. White.

TUESDAY, APRIL 5.

ROYAL INSTITUTION, at 3.—The Modern Development of the Problem of Alcoholic Fermentation: Dr. A. Harden, F.R.S.

ZOOLOGICAL SOCIETY, at 8.30.—On the Alimentary Tract of Certain Birds, and on the Mesenteric Relations of the Intestinal Loops: F. E. Beddard, F.R.S.—The Caudal Fin of the Teleostomi: R. H. Whitehouse.—Some Notes on Tasmanian Frogs: T. M. S. English.

INSTITUTION OF CIVIL ENGINEERS, at 8.—The New Clyde Bridge of the Caledonian Railway at Glasgow: D. A. Matheson.—The Queen Alexandra Bridge over the River Wear, Sunderland: F. C. Buscarlet and A. Hunter.

FARADAY SOCIETY, at 8.—The Nature of the Action of Dyeing: W. P. Dreaper.—The Electrical Theory of Dyeing: Prof. W. W. Haldane Gee and W. Harrison.

WEDNESDAY, APRIL 6.

SOCIETY OF PUBLIC ANALYSTS, at 8.—A Note on the Composition of the Milk yielded from Cows on a Pasture manured with Potash and Phosphates: J. Golding and S. G. Paine.—Note on the Influence of Solvents on the Drying of Linseed Oil: W. E. F. Powney.—An Improved Method for the Estimation of Titanium: A. Gemmell.—Extraneous Mineral Matter in Rice: F. W. Richardson.

ENTOMOLOGICAL SOCIETY, at 8.—On the Behaviour of Coleoptera during Floods: N. H. Joy.

THURSDAY, APRIL 7.

ROYAL INSTITUTION, at 3.—The Himalayan Region: Dr. Tom G. Longstaff.

LINNÆAN SOCIETY, at 8.—Elm-seedlings showing Mendelian Results: A. Henry.—On the Foraminifera and Ostracoda from Soundings, chiefly deep-water, collected round Funafuti by H.M.S. *Penguin*: F. Chapman.

RÖNTGEN SOCIETY, at 8.15.—Some methods of using the Alternating Current Mains for Röntgen Ray Work: Dr. G. B. Batten.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—The Progress of Electric Braking on the Glasgow Corporation Tramways: A. Gerrard.

FRIDAY, APRIL 8.

ROYAL INSTITUTION, at 9.—Lowell Observatory: Photographs of the Planets: Prof. Percival Lowell.

INSTITUTION OF CIVIL ENGINEERS, at 8.—The Reconstruction and Extension of Egremont Ferry Pier: G. H. Hodgson and H. M. Gell.

PHYSICAL SOCIETY, at 8.—An Experimental Demonstration of the Loading of Artificial Telephone Cables: B. S. Cohen.—Further Tests of Brittle Materials: W. A. Scoble.

ROYAL ASTRONOMICAL SOCIETY, at 5.

SATURDAY, APRIL 9.

ROYAL INSTITUTION, at 3.—Bells, Carillons and Chimes: W. W. Starmer.

THURSDAY, APRIL 7, 1910.

CRYSTALLOGRAPHY BY A PHYSICIST.

Cours de Physique. By Prof. H. Bouasse. Sixième partie, Etude des Symétries. Pp. 424. (Paris: Ch. Delagrave, n.d.) Price, 14 francs.

THIS sixth volume of the course of physics, prepared by the author to conform "aux programmes des Certificats et de l'Agrégation de Physique," deals with the subject of symmetry, both from the general physical standpoint and as it concerns crystals. The previous volumes have treated of mechanical physics, thermodynamics, electricity and magnetism, optics, and electro-optics. Besides actual symmetry, this ~~sixth~~ volume also discusses symmetrical deformation, double refraction in relation to the symmetry of crystals, the bearing of optical rotation on crystal symmetry, and a concluding brief account of liquid crystals. It presents many of the phenomena dealt with by the expert crystallographer from the very different outlook of the pure physicist, and such an outside view, by a competent authority, of a more or less special branch of science is usually of value, although one must not look either for specialised knowledge or intimate acquaintance with the phenomena described. In these days of specialists there are very few men able to deal without error with so many subjects as are included in the comprehensive course of Prof. Bouasse.

The reader is very much handicapped at the outset by the lack of any index, either of authors or subjects, but it is impossible not to be struck with the fact that the references to original investigations are almost entirely confined to those of French men of science. With the exception of a brief inevitable reference to Miller, whose notation was bound to be mentioned, we look in vain for any recognition of the many important contributions to our knowledge of both general and crystallographic symmetry which have been made during the last twenty years by British investigators, such as Maskelyne, Miers, Barlow, and Hilton, or of the large additions to chemical crystallography effected in this country. The work of Sohncke and Schönflies is referred to, and a passing mention of von Fedorow made, but anything approaching appreciation of the later most important work of the latter investigator and of Barlow is not forthcoming. Nor could any reference be found to the work on symmetry and crystal structure of Von Lang, Becke, Groth, or Muthmann. Gadolin is referred to, as he published in the French language, but the omission of British and Continental work to such an extent is a serious defect, as is also the fact that no references whatever to the literature of any original memoirs are vouchsafed.

Having accepted these limitations, however, and the further fact that practical details of crystallographic experimental work is not a feature of the book, an admirable summary of the work of Haüy, Lévy, Fresnel, Mallard, Bravais, Curie, Friedel, Bertrand, Sénarmont, and other French men of science, will be found. Moreover, when the author is

on his own ground of pure physics; and especially in the discussion of such parts of his subject as are not affected by recent foreign work, his matter is excellent, vigorously and interestingly expressed, incisive and clear. One of the most valuable parts of the book is the chapter on space-lattices, which includes a capital account of the immensely important, even fundamental, work of Bravais, work which only increases in value as the years roll on. It is followed by a good description of the theory of "groups of movements," which has resulted in our knowledge of the 230 types of homogeneous structures, based chiefly, however, on the treatise of Schönflies.

A considerable part of the book is also occupied with the physics of homogeneous deformations, although all mention of work on the thermal dilatation of crystals subsequent to that of Fizeau is omitted, and the treatment of elasticity and elastic deformations is purely theoretical and lacks any reference to recent experimental work.

When the author enters the domain of the crystallographer it is, unfortunately, to display a complete want of knowledge of the immense progress which has been made, largely by British workers, in experimental methods, in the preparation of crystals of a high degree of perfection for the purposes of investigation, and of the highly accurate measurements which have been made during the last twenty years on such perfect crystals. The important laws governing the relations between crystalline structure and chemical constitution, especially those relating to the effect of the interchange of the variable elements in isomorphous series, which has been the main outcome of this work, is entirely ignored. It is with great surprise that we read, referring to the use of even an ordinary goniometer provided with telescope and collimator:—

"Ce procédé de haute précision n'est presque jamais employé. C'est que les faces d'un cristal sont loin d'être des miroirs parfaits. Elles sont souvent de très petites dimensions. Elles présentent souvent des irrégularités, des stries. . . . Les faces sont souvent courbes. Enfin, c'est un fait remarquable, les angles des cristaux cristallographiquement les plus beaux ne sont les mêmes d'un échantillon à l'autre ou d'un angle à son homologue qu'avec une tolérance souvent énorme. Il faut entendre par là que, mesurant, avec toute la précision possible, le même dièdre sur une série d'échantillons, ou les dièdres homologues d'un échantillon, on trouve des résultats qui peuvent différer de plus de dix minutes. Pour toutes ces raisons, une précision extrême est illusoire; l'emploi du goniomètre ordinaire, toujours inutile, est dans bien des cas absolument impossible."

It is difficult to understand how anyone holding such opinions as to the value of exact work in crystallography should wish to write a text-book on the subject. It is not by disseminating such opinions that the study of crystallography can be advanced, and young students attracted to a richly repaying and almost unopened branch of scientific investigation. If the worker in crystallography is content to take the first crystal he alights upon as the best sample procurable, he will, of course, conclude as the author has done. But if he takes the trouble to obtain the most perfect

procurable crystals for his investigations, and, if they are artificial chemical preparations, if he has followed and makes use of the recent work on the preparation of perfect individual crystals, and the precautions to be taken to avoid disturbance during growth, there will be a very different story to tell, and the deformations, striations, curvings, and lack of constancy of ten minutes or more will all disappear, and the angles will inform him, if he employs the most accurate goniometer in the market, of their constancy to the last minute. To speak, moreover, of "petites dimensions" as being a drawback is even more enlightening as to the author's lack of familiarity with practical crystallography. For it is precisely small crystals, varying from a very small pea to a pin's head in size, that the crystallographer chooses by preference for his measurements. For the liability to distortion is then at its minimum.

Sufficient will have been said to indicate the excellences and the defects of this volume, both striking in their way. Indeed, in spite of the aggravating defects which it has been essential to point out, the writer possesses so original and lively a style, and his remarks are often so well worth reading, that with all its shortcomings, the book has good and valuable qualities, and in the portions where the author is on his own domain is both well written and instructive.

A. E. H. TUTTON.

THE ORIGIN OF THE DIAMOND.

Diamonds. By Sir William Crookes, F.R.S. Pp. xvi +146. (London and New York: Harper and Brothers, 1909.) Price 2s. 6d. net.

ALL who have had the pleasure of hearing Sir William Crookes's lectures on the diamond and its origin will be glad to find the valuable information contained in them put into a permanent form in the little book before us.

The author has had exceptional opportunities for studying the subject. During two visits to South Africa, in 1896 and 1905, he was allowed by the managers of the De Beers mines to have unrestricted access to valuable sources of information; and, as is so well known, his own physical and chemical researches have been largely concerned with questions connected with the properties and origin of the most remarkable, as well as the most highly prized, of the gems.

Concerning the Kimberley diamond mines, as well as the alluvial deposits of South Africa, Sir William Crookes can write with authority from his personal observations. As illustrating "the kind of speculative gambling" which goes on in the former class of workings, we are told of a claim where the owner had not seen a diamond for a fortnight, but just before then he had picked out a diamond worth 300l.! On the other hand, the systematic work at the mines of the De Beers Company enables the management to regulate the annual supply with the greatest nicety, so as not to cause any fall in the price of the gem. In 1907 more than two and a half million carats were raised, which realised 6,452,597l. The mode of occurrence of the diamonds, the methods of working

adopted at different times in the wonderful pipes that yield the gems, and the ingenious methods of treating the "blue ground" and sorting out the stones, are described and illustrated by photographs taken by the author himself.

Sir William Crookes had the opportunity of handling and taking a photograph of the celebrated "Cullinan diamond" before it was cut, and his description of it is of much interest. He tells us that:—

"A beam of polarised light passed in any direction through the stone, and then through an analyser, revealed colours in all cases, appearing brightest when the light passed along the greatest diameter—about 4 inches. Here the colours were very fine, but no regular figure was to be seen. Round a small black spot in the interior of the stone the colours were very vivid, changing and rotating round the spot as the analyser was turned. These observations indicated internal strain. The clearness throughout was remarkable, the stone being absolutely liquid like water, with the exception of a few flaws, dark graphitic spots, and coloured patches close to the outside. At one part near the surface there was an internal crack, showing well the colours of thin plates. At another point there was a milky, opaque mass, of a brown colour, with pieces of what looked like iron oxide. There were four cleavage planes of great smoothness and regularity. On other parts of the surface the crystalline structure was very marked. The edges were rounded in parts, and triangular markings (depressions) were to be seen. I also noticed square depressions, nearly as sharp and perfect as the triangular ones."

Interesting as this description undoubtedly is, we cannot but regret that, before this unique specimen was deprived of its interest for mineralogists by being cut, no opportunity was afforded to the author, or any other scientific investigator, of carrying out such a series of observations in the laboratory as would have enabled him to place on record all the facts about it which it was desirable to obtain.

A full account of the Cañon Diablo meteorite, with its enclosed diamonds, and of the vast crater-like depression in Arizona where it was found, is given in the concluding chapter. The author, in discussing the genesis of diamonds, is clearly of opinion that, whether of inter-terrestrial or of extra-terrestrial origin, the conclusion is established, both by observation and experiment, that the solvent from which the carbon has crystallised must have been molten iron.

In conclusion, we cannot but commend, to all desirous of learning what is known about the most beautiful and interesting of gems, this terse and attractive—but withal trustworthy and complete—summary of all the information on the subject which has up to the present been acquired. J. W. J.

DIFFERENTIAL GEOMETRY.

A Treatise on the Differential Geometry of Curves and Surfaces. By Prof. L. P. Eisenhart. Pp. xii + 474. (London and Boston: Ginn and Co., n.d.) Price 20s.

THE well-known works of Darboux and Bianchi are so excellent, each in its own way, that one might be inclined to doubt whether another text-book on the subject was really required—at least, for the

present. But Prof. Eisenhart's work will be acceptable to those who prefer English to other tongues, or who wish to have the main results in a more condensed form than that in which Darboux and Bianchi present them.

The author of this book has been remarkably successful in giving a large amount of matter without an appearance of stodginess. The main reason for this is that, besides having a crisp style, he is very judicious in omitting those links of connecting analysis which the reader can easily supply for himself, or take for granted as calculations which have been done once for all. Without any attempt to enumerate even all the principal topics discussed, it may be said that we have a sufficient account of curvilinear coordinates, conformal and other representations, differential parameters, and the Christoffel (or Riemann) symbols; chapters on the deformation of surfaces, including Minding's problem, and the method of Weingarten; a very compact account of geodesics, minimal and other special surfaces; and finally chapters on rectilinear congruences, cyclic systems, and triply orthogonal systems of surfaces. Incidentally, many elegant special applications are given; thus, for instance, there are several interesting theorems due to Bonnet.

One remark is almost sure to occur to the reader of the book, namely, that the use of the differential parameters of the linear element is, in some parts of the theory, a very powerful engine, at any rate, for purposes of condensation and lucidity. An instance of this will be found in the chapter on geodesics (pp. 215-8). No serious student of differential geometry can fail to read Gauss's famous memoir and the early papers by Lagrange and others on minimal surfaces; few things are more instructive than a comparison of these "path-breaking" memoirs with the compact and symmetrical methods of the present day. The contrast is so great that the student who hopes to do something himself is more than ever bound to read original papers besides text-books and treatises; otherwise he will be tempted to imagine that new results fall out of the sky, so to speak, in their final and clearest and most elegant shape.

Fortunately Prof. Eisenhart's book contains a partial antidote in the shape of a very useful collection of unsolved examples. These are of all grades of difficulty, ranging from simple corollaries to adjacent bookwork to important theorems extracted from original papers. It would, perhaps, have been a help in these latter cases to give a reference; but the author has been sparing in his bibliography, as indeed mathematical writers can now afford to be, when the "Encyclopædie d. Math. Wiss." and the Royal Society's "Subject Index" are available.

In conclusion, a word on notation may be permitted. The Christoffel symbols are so essential in some parts of the theory that they ought to be of a simpler character than they are; for instance, the formulæ on p. 155 may, in a sense, be expressive, but they are cumbrous and ugly in the extreme. Could not the Mathematical Congress, or some other body, suggest a simplified notation, with some chance of its being generally adopted?

G. B. M.

NO. 2110, VOL. 83]

THE INSPECTION OF FOOD.

Food Inspection. By Hugh A. Macewen. Pp. viii + 256. (London: Blackie and Son, Ltd., 1909.) Price 5s. net.

THIS work has been written with the object of giving a clear and concise account of the inspection of meat and other foods, and of the principles underlying the hygienic production of prepared foods. It embodies the author's personal experience of the methods employed in Berlin and other German towns, America, and Great Britain. The book, which is well illustrated, includes chapters upon meat inspection; the inspection of live animals, and the symptoms of the more important diseases from which they suffer; the methods of slaughter; the diseases commonly met with in the abattoir; the construction and management of slaughter-houses and abattoirs; the inspection of fish, poultry, game, fruit, and vegetables; the preservation and storage of food; the inspection of prepared foods; and the law relating to the above subjects. In the anatomical description given the ox is taken as the type, and whenever any of its organs or parts differ markedly from those of other animals which concern the meat inspector, a special description is given. Important anatomical facts include a clear statement and good illustrations of the situation of the principal lymphatic glands in cattle and pigs.

An interesting and useful appendix deals with the German method of meat inspection as carried out in Berlin, and another appendix furnishes a short description of Chicago stockyards and packing-houses, and of American methods of meat inspection. The writer condemns the private slaughter-house which is so general in this country. If inspection is to be efficient it is essential that the inspector should be present while the slaughtering is going on. This is impossible in all the private slaughter-houses; and therefore no adequate system of meat inspection is possible where they are suffered to exist. The organs of unsound animals may be concealed or destroyed before the inspector appears on the scene, and the writer testifies to the fact that there is often a marked want of cleanliness in the methods of dressing and preparing the meat in private slaughter-houses, which is not to be witnessed in public abattoirs.

The work will not serve as a reference book. The information offered is not comprehensive enough for that purpose; but it is admirably designed to provide what the average food inspector and public-health student requires from a text-book. In parts the matter will be judged by the medical reader as very elementary, but the book has been written mainly to meet the needs of non-medical readers; the former, however, will find a very great deal to interest and instruct. Indeed, it may be read with profit by all who are interested in the public food supply, and it will probably prove to be the most serviceable text-book which candidates preparing for the examinations for the food inspector's certificate, granted by the Royal Sanitary Institute and other bodies, may consult. Both in respect of the matter it contains and

to the manner in which the work has been produced by the publishers, it is a satisfactory and remarkably cheap publication, but the illustration of the head of *Cysticercus bovis* on p. 112 is quite unworthy of the book, and more information should be given on the important subject of the inspection of canned food.

A NEW CATALOGUE OF HEMIPTERA.

Catalogue of the Hemiptera (Heteroptera), with Biological and Anatomical References, Lists of Food-Plants and Parasites, &c. Prefaced by a Discussion on Nomenclature, and an Analytical Table of Families. Vol. i., Cimicidæ. By G. W. Kirkaldy. Pp. xl+392. (Berlin: Felix L. Dames, 1909.)

NOW that the study of entomology has become so widely extended, and of so much more importance, both medically and agriculturally, than was even suspected a few years ago, the publication of catalogues of the various orders and families of insects at frequent intervals has become an absolute necessity, for monographs and catalogues have become as indispensable to the study of any group of natural objects as are grammars and dictionaries to the study of a language. Often when a catalogue is published in several volumes, the stimulus to the study of the groups with which they deal is so great that the earlier ones are practically almost out of date before the later ones can be issued.

The last catalogue of the Hemiptera Heteroptera, by Lethierry and Severin, was not completed, though three volumes were published in 1893, 1894, and 1896, and therefore a new and complete catalogue was much wanted. Mr. Kirkaldy expected to complete it in six or seven volumes, of which this is the first. The second volume is stated to be in the press, and the third in active preparation.

Some years ago, the energetic author (who was a Scotchman) left the British Islands and went out to Honolulu, where he broke his leg, and it was probably this accident which gave him sufficient leisure to carry out so long and tedious a work as the present catalogue. We much regret that since the present volume was placed in our hands for review, we have received news of the death of the author at San Francisco, whither he had proceeded for an operation, which has terminated fatally.

Although we may not agree with all the author's dicta respecting nomenclature, his remarks on this difficult and intricate subject will be read with interest by students of other branches of zoology than that immediately concerned. There is also much information given respecting the bibliography, determination of types, and classification of the insects with which the author deals; and a table is given of the twenty-six families into which he divides the Heteroptera, of which only the first, Cimicidæ, is included in the present volume. The Cimicidæ are divided into ten subfamilies, as follows:—Cimicinae (=Asopinae), Pentatominae, Phyllocephalinae, Phlœinae, Dinidorinae, Cyrtocorinae, Scutellerinae, Aphylinae, Coptosominae (=Plataspinae), and Tesseratominae.

Four more families were intended to be included in vol. ii., and three more in vol. iii.

In addition to full references to genera and species (the latter arranged in alphabetical order under each genus), references are given to biological, anatomical, and general notes, and to descriptions of metamorphoses; lists of food-plants, parasites, predators, prey, &c., are added. Fossil species are included. The range is also given at unusual length, and tables are added giving the number of species of each genus found in the various geographical regions and sub-regions.

On the whole, this is an unusually comprehensive catalogue, and we hope that it will be possible to make arrangements for its completion, notwithstanding the untimely death of the author. W. F. K.

OUR BOOK SHELF.

British Wild Flowers in their Natural Colours and Form. By the Rev. Prof. G. Henslow. Pp. xii+318; with more than 200 coloured illustrations by Miss Grace Layton. (London: S.P.C.K., 1910.) Price 8s.

Flowers of the Field. By the late Rev. C. A. Johns. Entirely rewritten and revised by Prof. G. S. Boulger. 32nd edition. Pp. lii+926. (London: S.P.C.K., 1910.) Price 7s. 6d.

It appears that the publishers of Anne Pratt's "Wild Flowers," issued many years ago in two small volumes, have deemed it advisable to arrange a complete revision, which has resulted in the thick octavo volume forming the subject of this notice. The new title suggests that the illustrations, about 200 in number, are regarded as the leading feature of the book, but the descriptive text will be found no less attractive and well adapted for the less professional student of flowers for whom the book is chiefly intended. Apart from the fact that the Royal Horticultural Society awarded a silver flora medal to the artist, Miss Layton, it would be gathered from observation that the original drawings were correct and graceful representations of the wild flowers, but several of the reproductions are not very satisfactory in the matter of colour; to get the best effect, the plates should be examined by artificial light.

With regard to the subject-matter, so far as the plants described in the earlier work have been re-illustrated, the author has incorporated much of the original material; beyond that, he has drawn on his extensive store of botanical knowledge for the text to accompany the figures of plants now introduced, and for the additional space consequent upon the increased size of the book. The information supplied refers to the characters of the selected and allied plants, and to the etymology of their names; also medicinal or economic uses and striking morphological features are noted. There are some discrepancies in the details regarding cultivated plants. Thus, the tree from which gamboge is obtained now passes as *Garcinia morella*; the pistillate plant of *Garrya* has been introduced into this country and cultivated at Kew for some years; further, there is reason to hope that the cultivation of indigo in India will not go under, as some users of the dye find it superior to the synthetic article.

Two more important features should be noticed; these are the inclusion of a synopsis of the families represented and the arrangement which follows the sequence of Bentham and Hooker; the glossary of technical terms will also be useful. It will be found that the reconstructed work is fuller and more scien-

tific than the original, which, however, served a very useful purpose in the past.

A new edition of Johns's "Flowers of the Field" differs only from the last remodelled version, published in 1905, by the addition of the coloured plates. This addition is obviously a concession to the modern practice of supplying illustrations in colour. The drawing of the plants is good, but the colour and printing are uneven in the reproduction.

Dynamo Laboratory Manual for Colleges and Technical Schools. Vol. I., Direct-current Studies and Tests. By W. S. Franklin and W. Esty, with the cooperation of S. E. Seyfert and C. E. Clewell. Pp. viii+152. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1909.) Price 7s. 6d. net.

THE advisability of publishing a laboratory manual which consists practically only of a reprint of the instructions given to the students in a particular college or university is a matter that is open to question. It may be objected that the instructions can only be of real value to those who have an equipment exactly the same as that in the laboratory of the authors, a coincidence that is likely to be rare, and that each teacher will preferably use instructions of his own, drawn up to suit the circumstances of his case. On the other hand, it may fairly be contended that such publications are of special value to teachers in that they enable them to compare their own methods with other people's, and to modify and improve their own courses as a result. From this point of view this volume, in common with others of the same kind, must be regarded as rather of value to the teacher than to the student. Indeed, as the instructions without the experiments are like the white of an egg without salt, the student can gain little from the present volume unless it is adopted by his teacher.

The volume deals only with direct-current machines. There is a short introduction dealing with general methods of measurement, &c., and the remainder of the book is divided into three parts, each describing sixteen tests. The experiments seem well chosen so as to bring out the more important points in direct-current dynamo work, and the instructions are full, if anything too full. There are a large number of clear diagrams.

The authors admit in their preface that their leaning is towards the purely pedagogical aspects of laboratory work; it is hardly the place in a review of a book written frankly on this basis to discuss whether this aspect is the best one, and it need only be said that, granting this premise, the course indicated in the volume before us seems admirably suited to get the most out of the laboratory training.

Mona's Records of the Earth's Changes. By Joseph Lewin. Pp. iv+100. (Douglas: Brown and Sons, Ltd., 1909.)

THIS is not, as might be supposed, a popular sketch of the geology of the Isle of Man. It is a description of certain highly hypothetical changes in the relations of sea and land that are held to have taken place within historic times. Five successive lowerings of the sea are said to have left their traces in wave-worn terraces, and these records were all formed in the last 2000 years (p. 39). Seeing that the Mona of Tacitus (p. 2) is moved by the author from Anglesey to the Isle of Man, we may well have doubts as to his historic judgment. One of the withdrawals of the sea is placed in 1538, so as to coincide with the enlargement of the shore near Pozzuoli; and such changes are attributed to movements of the axis of rotation of the earth, or to movements of the shell of the earth over

the axis of rotation. The author does not seem quite clear as to which of these he adopts; but his context usually conveys the latter impression. His style may be gauged from the following portion of a sentence, the whole being too long for quotation (p. 94):—"But, according to the wobbling state of the poles of our earth at present, as described by our scientists at the earthquake, that caused so much damage and loss of life at Messina, as described in the *Daily Mail*, our earth at any moment, with another great earthquake, may lose its centre of gravity at the Poles, and move again slightly in the same direction as it has already done. . . ."

The general underlying conception is that the British Isles are being carried nearer to the North Pole, and away from the bulge of waters round equatorial regions. Palestine (p. 99) is to profit by the next change, which is due in a few years. There are some interesting scraps from old chronicles throughout the book, which save it from being judged too severely as a scientific treatise. G. A. J. C.

Ancient Angling Authors. By W. J. Turrell. Pp. xiii+239. (London: Gurney and Jackson, 1910.) Price 3s. 6d. net.

IT is fortunate that our English ancestors did not all agree with Plutarch in regarding fishing "as a filthy, base, illiberal employment," for the works which they have left us in praise and honour of the angler's art contain a valuable history of both tackle and methods. The fisherman has for a long time enjoyed a poor reputation for truthfulness, and Mr. Turrell exposes the angling author as a most unblushing plagiarist; but in spite of these shortcomings they are both excellent companions.

The respectable antiquity of many methods, reputable and otherwise, practised to-day is certainly remarkable; in 1657 one Barker had already discovered the use of salmon-roe as a bait, and salmon-fishing with the prawn was known in 1740. While Cotton (1676) may claim the credit of first describing how to take trout in clear water with the worm, the exact history of dry-fly fishing appears obscure, and cannot be definitely traced beyond the early part of the eighteenth century. So long ago as 1600, Taverner was recommending that fish-ponds should lie dry every other year, as is, we believe, the modern German practice, and ten years earlier Mascall had discussed the best methods of preserving fish.

There is, however, one habit of our ancestors which we have fortunately abandoned, to wit the anointing of our baits with strange and horrible unguents to attract the fish; from the beginning of the seventeenth to the middle of the eighteenth century recipes for the compounding of these form part and parcel of the current angling literature, and it is small wonder that these medleys of man's fat, cat's fat, assafoetida, mummy dust, and turpentine called forth the anger of Dr. Martin Lluelyn on those whose

"pastes fox Rivers throat, . . .
That from May to parcht October
Scare a Minew can sleepe sober."

With the help of Mr. Turrell's little work and its really admirable index, much further information as to the early history of various parts of the angler's equipment and the different forms of his art may be readily gleaned, and the various subjects touched upon will be found to be explained by copious extracts from contemporary books. Nor must it be supposed that we are dealing with a mere compilation; Mr. Turrell has obviously gone to the very fountain-head for his information, and he is at times able to correct the errors of his predecessors and to throw fresh light upon doubtful points.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. No notice is taken of anonymous communications.]

The Term "Radian" in Trigonometry.

FROM a recently published part of the "New English Dictionary" it is to be inferred that the first authority for the use of the word "radian" was the "Treatise on Natural Philosophy" of Thomson and Tait, the date given being 1879—that is to say, the date of the new edition of part i. of vol. i. As the word has at least ten years of previous history, it may be desirable to put on record a few additional facts in regard to it. My own first use of it was in class-teaching in the College Hall at St. Andrews in 1869, and I possess a note-book, belonging to one of my students of that year, in which the word is used. The introduction of it was almost simultaneous with my proposal of the word "therm" in connection with the measurement of heat.

The advantages of the latter word I went so far as to point out in a letter to NATURE dated almost exactly forty years ago (see vol. i., p. 606). At that time I was inclined to suggest the form "rad" in preference to "radial" or "radian," it being advantageous to have a monosyllable for the fundamental unit of a series if auxiliary units like "kilotherm," "millirad," &c., were likely to be called for (see NATURE, vol. iii., p. 426).

It was in 1874, after several conversations on this and similar subjects with the late Prof. James Thomson, of Glasgow, and especially after an exchange of letters with the late Alexander J. Ellis, that the form "radian" was definitely adopted by me. In that year I came across the following passage in an interesting historico-biographical note written by Ellis as an appendix to his "Algebra Identified with Geometry" (London, 1874):—"Let u be a unit-line, then; if r and ζ be both real numbers, $resu$ represents a line of the length ru and inclined to u at ζ radial angles" (p. 82), there being added in brackets the definition " 2π radial angles = 4 right angles." As a consequence I wrote to him, and he declared at once for the form "radian," on the ground that it could be viewed as a contraction for "radial angle" in accordance with precedents in chemistry which he had himself followed in his nomenclature of the so-called "stigmatic" geometry. He also incidentally mentioned that he had used the expression "radial angle" from his Cambridge undergraduate days.

THOS. MUIR.

Cape Town, South Africa, March 6.

The Fertilising Influence of Sunlight.

THE letters on the above subject in NATURE of February 17 and March 3 and 10 are of much interest. In many parts of the world artificial heating of the soil is a regular practice. For example, in the rice districts of heavy rainfall in the Bombay Presidency the seed-bed for transplanted rice and some small millets is almost invariably subjected to a process known in the vernacular as "rab." This consists of spreading a layer of branches, grass, cow-dung, &c., over the surface of the plot (often only a few metres square) selected as the site of the seed-bed. This material is then slowly burnt before the breaking of the monsoon.

There is a general agreement as to which kind of "rab" is best, that consisting largely of cow-dung (in the form of a plaster with chopped straw) being considered by far the best. Then comes that composed of the branches of certain species of Terminalia, after which come those of any available trees, and finally that composed of dried grass.

An experiment I conducted on these materials in the year 1906-7 at Lanowli, in the rice district above the Ghats between Bombay and Poona, gave the results stated below. Unfortunately, an untimely shower fell a few days before the material was burnt, so that the temperature of the soil was probably not raised so high as in ordinary seasons; this temperature was taken by scraping off the

ashes at various points and inserting a thermometer 3 or 4 centimetres into the soil immediately after burning; it varied between 200° and 230° F.

The material was prepared and burnt in the ordinary method used by the natives; in addition, plots were added, one of which was manured with safflower (*Carthama tinctoria*) cake, another with cow-dung, another with ashes scraped off a "rabed" plot, while in a fourth the soil was finely pulverised to a depth of about 8 cm., and in a fifth the surface soil was removed to this depth, placed on iron sheets, and heated from beneath until a temperature of 200° to 230° F. was reached, when it was allowed to cool.

At the time of transplanting, twenty average seedlings were taken from each of the plots, dried, and weighed.

The results were as follows:—

Treatment of plot	Average dry weight of seedlings (in grams) in each of the triplicate plots			Mean
	A	B	C	
1. Manured with safflower cake.	0'4097	0'4967	—	0'4532
2. "Rabed" with branches of Terminalia	0'0879	0'0879	—	0'0879
3. "Rabed" with mixed branches	0'2181	0'1708	0'1430	0'1773
4. Manured with ashes of mixed branches	0'0797	0'1094	0'0954	0'0948
5. Manured with cow-dung	0'0928	0'0772	—	0'0850
6. "Rabed" with cow-dung	0'2561	0'3172	—	0'2866
7. Soil pulverised	0'0909	0'0625	0'1000	0'0845
8. Soil heated	0'3562	0'2968	0'2276	0'2935

It should be noted that owing to scarcity of this material at the time sufficient branches of Terminalia could not be obtained even for the single plot. Hence, probably, the poor result on this plot.

From the above it will be seen that the *raison d'être* of this process is to obtain the effect of heat, and neither to improve the physical condition of the soil (cf. plots 7 and 8) nor to supply plant food (see plots 4 and 5). The ashes have practically no value, and the natives state that it is of no consequence when the ashes, as is often the case, are removed by wind.

The enormous effect of safflower cake is well known, an application to sugar-cane being many times more efficient than that of any other cake when applied to give equal quantities of nitrogen. The reason for this is under investigation.

The fertilising effect of heat on soils has been known for ages, as witness the ancient practice above detailed. That, however, it is due to the causes assigned by Drs. Russell and Hutchinson, viz. a partial sterilisation of the soil, is very much open to doubt. In their extremely interesting work at Rothamsted they find an increase in bacterial activity and rate of increased decomposition of organic matter after partial sterilisation associated with an increased crop yield. There is the possibility, however, that these latter phenomena are accompaniments, and not the causes, of the increased crop-yields, all being the result of a destruction of toxic material in the soil. In any case, the theory put forward is apparently incapable of explaining many causes of sterility in soil, and is, apparently, not a general explanation that has any practical bearing on the general question of soil fertility. For example, it is difficult to see how it can account for the fact that certain plants will not grow in the immediate neighbourhood of others, as the present writer has found to be the case ("Memoirs of the Department of Agriculture in India," Bot. Ser., vol. xi., No. 3, April, 1908).

The excellent work of the U.S. Bureau of Soils has proved that roots of plants excrete a toxic substance. The present writer has noted the same phenomenon, and has further isolated the substance from water in which plants have been cultivated. A further paper on this question is in preparation. It may, however, be stated here that if water rendered toxic by the growth in it of plants is shaken with benzene, toluene, chloroform, or carbon bisulphide (the antiseptics used in experiments for partially sterilising soil), this toxic substance is rendered insoluble, and therefore innocuous.

As an example, when such water is shaken with toluene, an emulsion is formed which floats on the surface of the water. If this emulsion is poured off and the toluene and water allowed to evaporate, a residue is left

which is not soluble in water (or at least not in the quantity of water from which it was extracted).

It therefore appears probable that the effect of toluene on the soil is to render insoluble and innocuous this toxic substance. Similarly with the other antiseptics mentioned; ether apparently does not convert the substance into an insoluble form, and its method of acting is being investigated.

The writer has also found that heating to dryness on a water-bath decomposes this substance, and it is probable when in the soil that a lower temperature will suffice. It seems probable, therefore, that the fertilising effect of sunlight will be found to be due to the decomposition of this toxic substance.

F. FLETCHER.

TRANSCASPIAN ARCHÆOLOGY.¹

IN the two volumes referred to below are incorporated the results of the American expedition which visited Russian Turkestan under the direction of Mr. Raphael Pumpelly, the well-known geologist, in 1904, and, besides conducting excavations at Anau, near Askhabad, collected material bearing on the physiography of the Central Asian deserts and oases. Thus the work of the expedition was two-fold. On one hand, we are presented with geological and physiographical observations, illustrating changes which have taken place in the character of Central Asia; on the other, we have a full and able presentment of the archæological material obtained from the excavations at Anau, including a very complete ceramic record. We should add that the excavations were directed by Dr. Hubert Schmidt, of Berlin, who joined the staff of the expedition for that purpose.

On the physical side, Mr. Pumpelly, assisted by Messrs. Davis, Huntington, and R. W. Pumpelly, who were also members of the expedition, found traces in High Asia of several great glacial expansions during the Glacial period. According to the picture which he gives us, there existed a cap of continental ice, thousands of feet thick, which spread over nearly the whole of European Russia; and Central Asia was covered by a huge inland sea, larger than the Mediterranean, and fed by rivers flowing from the snow and ice. The sub-Glacial period was marked by a general trend towards desolation, accompanied by the disappearance of the ice-cap from Russia and a diminution of the great glaciers on the southern mountains. As evaporation became more rapid than the inflow of water, the inland sea shrunk and broke up into smaller basins, and the dried silts of seas and rivers were carried by the wind in great columns of dust across the earth. The lightest material was carried farthest, and deposited in beds of loess, the extraordinarily fine and fertile soil which covers a great part of the surface of Northern China and Turkestan, and extends in a continuous zone from north of the Caspian to Austria. The heavier

silts, in the form of sands, moved more slowly along the surface of the plains, where they formed great seas of sand-dunes, heaped up in places to a height of more than a hundred feet. We may note that to the shifting of such sand-deserts in historic times we owe the burial of cities in the Khotan region, which have been so successfully excavated by Dr. Stein for the Indian Government. With regard to the geological side of his work, we certainly think that Mr. Pumpelly's researches on the spot tend to confirm Richtenhofen's theory of the wind-borne origin of loess, and he has succeeded in obtaining further evidence of his own modification of the theory as to the important part played by river silts, and the chemical action of vegetation, in furnishing the constituents of loess.

As a deduction from his archæological researches, Mr. Pumpelly would regard the Central Asian oases as the fountain-head of Western Asiatic culture. According to his theory, their inhabitants were isolated from Africa and Europe from the Glacial period onward, and their cultural requirements were consequently evolved in complete independence. Changes in climatic conditions, however, took place, under

FIG. 1.—(1) The North Kurgan at Anau, in Russian Turkestan, with the Camp of the Pumpelly Expedition in the foreground. (2) The South Kurgan at Anau, showing excavations in progress.

which the early civilisations in these regions tended to disappear, and these gave rise to extensive migrations, which eventually reacted on the outside world. In support of his theory, Mr. Pumpelly would trace the early appearance of wheat and barley in Babylonia and Egypt, and the presence of certain breeds of domestic animals, to their first establishment in the Transcaspian oases. Moreover, he would place the original home of the Sumerians in Central Asia, where, before their arrival in Babylonia and their subsequent fusion with Semitic nomads, he pictures them as having already acquired the elements of their racial culture and organisation under the stern discipline of a struggle with nature. The absence of any form of writing in the mounds of Anau may be cited as negative evidence against any racial, or even cultural, connection with the Sumerians, though, as we shall see later, a study of the ceramic points to some influence having been exerted from that quarter on the early cultures of Susa in Elam.

In this connection it is indeed a moot point whether the parent civilisation was not that of Elam herself.

¹ Explorations in Turkestan: Expedition of 1904. Prehistoric Civilisations of Anau. Origins, Growth, and Influence of Environment. Edited by Raphael Pumpelly. Vol. I, pp. xxxvi+230+vi; vol. II, pp. x+(241-494)+x; with 97 plates and 548 illustrations, including maps and plans. (Washington: Carnegie Institution, 1908.)

It would be tempting to seek the origins of the Babylonian and Elamite cultures in the highlands of Asia, for it is not difficult to assign causes for a succession of migrations westward. The nomad population of Central Asia, swollen to the limit of the supporting capacity of its pasture lands, would be forced to seek outlets into more favoured regions. This process may well have been accelerated by periods of drought, due to the climatic changes which have left no uncertain traces behind them in the character of the country itself. The present condition of aridity would appear to have been of continual growth, with certain oscillations, since the Glacial period. Already in prehistoric times the seas of sand-dunes had en-

croached upon the fertile plains of loess, and the delta-oases, at the mouths of streams emerging from the mountains, or at points where larger rivers lost themselves on the surface of the plains, have been the favourite home of man. It was at one of these, at Anau, near Askhabad, some three hundred miles east of the Caspian, that the Pumpelly expedition conducted excavations in 1904, and obtained its principal material for archaeological study.

Near the middle of the Anau oasis, and about a mile from one another, are the two Kurgans, hills with rounded contours, rising some forty and fifty

feet above the plain, and marking the sites of long-forgotten cities. The structure of the North Kurgan had already been exposed by a trench cut in it some twenty-five years ago by General Komorof, which showed a series of stratified remains, including the bones of animals and potsherds of plain and painted ware. It was this trench which first directed Mr. Pumpelly's attention to the mound, and his subsequent excavations, both here and in the South Kurgan, laid bare a stratified structure of precisely similar character. The strata represented successive occupations of the sites, and, as their inhabitants lived in houses built of sun-dried brick, the hills gradually rose in height by the accumulation of *débris* from previous settlements. Of the two hills, the North Kurgan was of earliest formation, its earlier strata representing a Stone-age culture, while its upper layers belong to an æneolithic stage of civilisation. The third culture, that of the South Kurgan, dates from a Copper age. The archaeological part of the work was left wholly to Dr. Schmidt, assisted by Miss Brooks, and to his admirable method of noting the precise spot and level of every object recovered we owe the possibility of tracing the gradual development of culture during the successive periods of settlement. Moreover, the Transcaspian Railway passes little more than half a mile to the north of the North Kurgan, so that no difficulty and little risk were involved in the conveyance to Europe of all the archaeological material obtained. The collection of animal bones from the North Kurgan alone weighed nearly half a ton, but the neighbourhood of the railway enabled the whole collection to be transported without trouble to Dr. Duerst, of Zürich, who contributes a report on them as part vi. in the second volume.

The cultural progress of the three great periods is most clearly revealed by the pottery, which exhibits a gradual evolution in form, technique, and decoration. Although the vessels of the first two cultures are hand-made, and the wheel was not introduced until the advent of the Copper age, yet the vessels of both earlier epochs are excellent ceramic productions. It would be out of place in the present review to discuss in detail the problems presented by a study of the potsherds, so admirably edited by Dr. Schmidt; but it may be noted that many of the geometric designs occurring on pottery of the earlier periods from North Kurgan bear a striking resemblance to designs on pottery found by MM. Gautier and Lampre at Mussian, and by M. de Morgan at Susa. This may well point to some connection between the stone and early metal-using cultures of Transcaspia and Elam, while the baked clay figurines from the copper culture of South Kurgan may be due to some early cultural contact with Babylonia, as first suggested by Prof. Sayce. Whether we may treat as significant a further resemblance which has recently been pointed out by Mr. H. R. Hall between the Persian and Transcaspian sherds, on the one side; and fragments of similar geometric pottery on sites in Asia Minor and even in Northern Greece, is a subject outside the scope of the present review. That such problems should be even mooted is a sufficient testimony to the importance of the archaeological material obtained by the Pumpelly expedition.

In fact, Mr. Pumpelly, though not an archaeologist himself, has, with Dr. Schmidt's valuable cooperation, produced a work of the first importance to students of archaeology. In the first five chapters of part i. of the first volume he has admirably summarised the results obtained by the expedition, but there is one feature of his treatment to which we feel we

must take exception. Mr. Pumpelly's attitude with regard to prehistoric chronology is indicated by the remark with which he introduces his description of the sub-Glacial period in Central Asia. "Remember," he says, "that while we look, in our time-perspective, millenniums are as seconds." This generous and imaginative method of treating the lapse of time, which is no doubt a very necessary virtue in the geologist, is wholly destructive of an accurate chronology in archaeological study. Moreover, the attempt to apply geological methods of dating to the purely artificial growth of a city site is totally unscientific, and we are glad to note from a remark at the end of Mr. Pumpelly's preface that he has already realised the possibility of error in at least one of his assumptions. Such dates as 8000 B.C., which he suggests for the beginning of the Neolithic settlement at North Kurgan, or 5000 B.C., for the beginning of the Copper age in South Kurgan, are wholly fanciful. It is true that very early dates were at one time in

SOURD MILK: ITS NATURE, PREPARATION, AND USES.

THERE seems to be little doubt that as age advances the microbial flora of the human intestine, especially of the lower portion or large intestine, often undergoes a change both in the number and in the character of the micro-organisms present. From middle life onwards the number of microbes increases, and species capable of inducing putrefactive decomposition of proteins become more abundant. This change can be roughly gauged by making microscopical preparations of the dejecta and staining by the Gram process, a selective method by which certain organisms only are stained. In the child's dejecta Gram-staining microbes are relatively scanty and are mostly *Bacillus bifidus* and *B. acidophilus*, and it is noteworthy that these are lactic-acid producing bacilli. In and after middle life Gram-staining forms usually become more and more numerous, the Gram-staining species now being principally *Bacillus putrificus* and *B. Welchii*, bacteria which induce marked putrefactive decomposition of proteins.¹ In unhealthy conditions of the intestinal tract somewhat similar changes or various abnormal fermentations may occur.

Metchnikoff² in a study of the nature of senility formulated the hypothesis that it is caused, partially at least, by auto-intoxication, poisoning by the absorption of products derived from the action of micro-organisms in the digestive tract. Such poisons would be the products of the putrefactive decompositions brought about by the micro-organisms named, and also bodies belonging to the phenol series which are formed by the action of *Bacillus coli*, which is always present in the intestines, becomes more and more numerous from youth to old age, and which also multiplies excessively in unhealthy conditions of the digestive tract. In seeking for some agent which would combat the multiplication of micro-organisms in the intestine, particularly these harmful

forms, Metchnikoff conceived that lactic acid, which has no deleterious action in the human economy, would probably effect the end desired, since the growth of these bacteria is inhibited by a moderate percentage of this acid. Bienstock, for example, found that the *B. putrificus* is inhibited in growth by *B. coli* thanks to its acid-producing power, the acid formed, though small in amount, being lactic acid. Simply to introduce the acid as such would, however, be of little use, for it would be absorbed and decomposed long before it reached the large intestine. Metchnikoff therefore sought for some means whereby lactic acid might be formed *in situ*, and naturally fell back on the use of lactic-acid-producing bacteria, which, if they could be established in the large intestine, might there produce sufficient lactic acid to inhibit the growth of the putrefactive and other deleterious forms. But the problem was not an easy one, for it entailed the finding of a lactic acid ferment which would grow at body tem-

FIG. 3.—Terracotta figurines from the Copper Age Stratum (Culture III.) at Anau, suggesting a cultural connection with Babylonia. From the South Kurgan.

vogue, both in Egyptian and more particularly in Babylonian archaeology; but these are now given up, and it is recognised that the earliest Sumerian remains in Babylonia do not date from an earlier period than the end of the fourth millennium B.C., while the Neolithic remains at Susa are probably not of a very much earlier period. While these facts naturally affect the dates suggested by Mr. Pumpelly for the cultures at Anau, they do not in any way upset their relative arrangement. It is perhaps significant that Dr. Schmidt nowhere mentions a date; and throughout the whole work the material is presented in such a way that the student is in no way hampered or misled.

The success of the expedition, and the admirable volumes which set forth its achievements and results, are a striking testimony to Mr. Pumpelly's enthusiasm and powers of organisation, and at the same time show the high scientific aims and standards which inspire American archaeological and geological research at the present time.

² "On the Prolongation of Human Life."

perature (99° F.) and maintain itself in spite of the competition of the other micro-organisms present. The ordinary lactic acid ferments found in milk grow best at 75°-85° F., and are unsuitable.

Metchnikoff says¹ "I had no illusion as to the difficulty sure to be encountered in any effort to introduce lactic microbes into the intestinal flora which has been preoccupied by a multitude of other microbes. To make surer of the result, I chose the lactic microbe which is the strongest as an acid producer. It is found in the *Yoghurt*, which originates in Bulgaria. The same bacillus has also been isolated from the *leben* of Egypt; and it is now proved that it is found in the curdled milk of the whole Balkan peninsula, and even in the Don region of Russia." Metchnikoff also noted that some of those who consumed a diet of little else than the soured milk lived to an advanced age. This then was the origin of the use of Bulgarian sour milk, and of the introduction of artificial substitutes for the natural article. It may be added that the use of sour milk seems to be widespread in the East, for it is found also in Turkey, Siberia, and Asia Minor, and in India under the name of "Dadhi."² As Chaterjee says, "The extensive use of one or other varieties of fermented milk, produced by means of a special ferment in Eastern countries, probably owes its origin to the difficulty of preserving milk in a sweet condition for a long time, in comparison to cold countries; milk when undergoing spontaneous decomposition in hot climates becomes changed within a few hours to a foul-smelling fluid in which the casein and the fat have undergone liquefaction, whereas, when fermented by means of the special ferment the decomposing, gas-producing, proteolytic bacilli are killed off by the more vigorous organism of the ferment, which has no destructive action on the fatty or albuminous constituents of milk, so that by this means milk can be kept in a condition fit for consumption for a long time."

The bacteriology of the various natural sour milks is somewhat complex and not yet fully elucidated, although considerable research has been devoted to it. Micro-organisms of a peculiar type are present in all. One of the first to be isolated was the *Bacillus bulgaricus*, a large Gram-staining, non-sporing, rod-shaped organism, which grows best at temperatures between 110° F. and 120° F. Development, however, is slow even at the optimum temperature, taking three days for the maximum production of lactic acid in milk, and it is therefore unsuited for the preparation of artificial soured milk. Another organism is the "granule bacillus" (*Körnchenbacillus*) of Kuntze. This is probably the organism so often spoken of as the "bacillus of Massol," and is widely used for the preparation of soured milk, as it grows rapidly and well at a temperature of about 100° F. and produces a relatively high percentage of lactic acid. The name of "granule bacillus" is derived from the fact that granules which stain deeply are present in the bacterial cell. In all the natural soured milks somewhat similar micro-organisms are to be found. It is of interest that Kuntze has suggested that these Bulgarian lactic ferments are allied to the *B. acidophilus* and *B. bifidus*, which, as already stated, are present in the child's intestine, and they are probably primarily of intestinal origin.

In natural sour milks the special lactic acid ferments are always associated with other ordinary lactic acid bacteria, particularly a *Streptococcus* (*S. lacticus*), and a mixed culture of this last-named organism with the bacillus of Massol, presents advantages over the

use of the latter alone.¹ For instance, when the *B. bulgaricus* grows alone in milk it has some effect on the fat, producing small quantities of nauseous tasting substances, but Metchnikoff has shown that this result is entirely obviated by a symbiotic growth with an ordinary lactic acid organism. The ingestion of milk soured by an ordinary lactic acid organism also tends to produce in the intestine an acid environment which favours the growth and persistence of the special lactic ferment, the bacillus of Massol.

Various procedures are adopted for the preparation of the natural sour milks. According to one account, *Yoghurt* is prepared by boiling milk until it has diminished to half its volume by evaporation, it is then allowed to cool somewhat and a little of a previously prepared sour milk is added and the whole allowed to stand in a warm place until next day. Another method is to wipe round a wooden bowl with a piece of cheese (presumably prepared with the sour milk) and then to introduce into the bowl the boiled milk. *Dadhi* is prepared by boiling milk, for some time, cooling to blood-heat, and then inoculating with a needle dipped in a former brew. The inoculated milk is covered with a blanket and kept in a warm place for 12 hours.

For the artificial production of soured milks the milk is well boiled in order to sterilise it and destroy undesirable organisms, and when it has cooled sufficiently a "starter" consisting of a pure culture of the proper lactic ferments is added. The inoculated milk is then kept at 100° F. or thereabouts for from 10 to 24 hours, according to the amount of starter added, and should then be fit for use. Many "starters," both liquid and solid (tablets), are to be had, but only a few are to be recommended, as some are grossly contaminated with undesirable bacteria. Another method is to add a little of the previous day's preparation to the milk to be soured. Some of the large dairy companies also supply the soured milk ready for consumption.

Considerable care must be exercised in preparation to use sterilised vessels and to safeguard the milk from contamination during incubation. The milk properly prepared should be thoroughly curdled, possess a not unpleasant tart flavour, and have a marked acid reaction. Some of the older "starters" contained sporing bacilli which though they curdled the milk (owing to tryptic ferments) gave rise to little or no acidity. Preparations containing a combination of the bacillus of Massol, with *Streptococcus lacticus* or *lebenis*, are probably the most suitable.

The internal administration of tablets, &c., containing the lactic ferments, in place of the soured milk, is of questionable utility.

Although some are still sceptical as to the value of soured milk, it can hardly be doubted that it is beneficial in many complaints.² Among these are (a) those depending on abnormal putrefaction of proteins in the intestinal tract, and including certain cases of acute enteritis and acute and chronic colitis; (b) auto-intoxication, with products of intestinal putrefaction, as in many cases of general failure of health in elderly persons, forms of anæmia, neurasthenia, with flatulent dyspepsia, &c.; in minor ailments such as lassitude, headache, some forms of constipation and diarrhoea, rheumatic pains, and the like, benefit frequently results. It must also be recognised that even if the soured milk as such does little good, it often enables an addition of valuable and easily assimilable

food-stuff to be made to the diet by its use. On the other hand, soured milk is by no means a universal panacea, and should not be taken indiscriminately without medical advice, as it sometimes disagrees.

Moreover, the home preparation of soured milk cannot be recommended unless it is undertaken by a member of the household having some knowledge of the scientific principles involved in the practice of sterilisation and use of pure cultures.

R. T. HEWLETT.

CLASSICS AND SCIENCE IN EDUCATION.

THE recent correspondence in *The Times* on the question of "compulsory Greek" at Oxford chiefly refers to academic expediency and the establishment of a *modus vivendi* between the Oxford tradition and the claims of scientific students. But the vital and ultimate question is not this detail of practical politics; it is the question of the fundamental principles of education. The recrudescence of the "Greek controversy" is important, as showing how social evolution is gradually forcing education—however unconscious educationists may be of the fact—along the lines of progress.

The issue at Oxford is between the classical or "literary" test, as a guarantee of the classical or "literary" foundation (or "character," it may be said) of the whole system of Oxford studies, and the interests of "the large body of scientific and other workers to whom literary studies are difficult and tiresome, and to whom the examination in Greek is a mere 'obstacle.'" We quote the words of Prof. Turner; he adds that, in his opinion, "Greek is as important to a literary education as mathematics to a scientific. In neither case is the particular study essential, but it is of vast importance." Dr. Jackson points out that "in many of the university studies the highest proficiency cannot be obtained without a knowledge of Greek. For the highest proficiency in mathematics or any branch of science Greek is not, but modern languages are, a necessity."

In connection with this reference to proficiency, a proposal was recently made that Greek should be retained where it is essential for a complete mastery of the subject, but that where it is not essential an alternative which ensured a certain amount of "literary culture" might be allowed.

Such a test is meant to safeguard the Oxford principle of a "literary" or humanistic foundation for all its studies. With this principle is supposed to be bound up "the Oxford spirit."

If this principle is interpreted to mean that the study of science, for example, should be preceded or accompanied by a training in the arts of language which are necessary for complete power of expression and for the development of that side of the mind which is built up by language, the principle is sound. But if it is made to mean the educational necessity of "culture," in the sense of a literary, rhetorical, or æsthetic habit of mind or refinement of "taste," one must protest. The former has no general applicability to education; it is merely a result of specialising upon literary, rhetorical, or æsthetic material. As for the latter, mental refinement is as much a result of scientific as of literary or classical studies. It is a manifestation of the critical, that is, of the scientific habit.

As a test of this, a general training in science would be at least as effective as the study of a special subject such as Greek. And, to take another point of view, a study of physical phenomena and of their relation to human life and history is essential to both complete mental development and a liberal education. To confuse these last with a "literary" or humanistic

tone or curriculum is to confuse general development and general education with specialisation.

Greek is essential to a study of literature or to a complete literary training, but to nothing else. But even supposing that it were necessary for a liberal education, and therefore desirable for scientific students, it is obvious that the standard of Greek required for entrance at Oxford is ludicrously inadequate; it is absolutely no test of anything except of a *beginning* in the study of a particular language.

It is as well to be clear on the meaning of the term "literary." As used in this controversy and with reference to the "Oxford spirit," the term implies rather that form of liberal education which consists mainly in a rhetorical philosophy of politics, history, law, and literature than a literary education proper. Even for this form of liberal education a knowledge of the Greek language, however high the standard attained, would not be essential. Greek, as we have said, is only essential to a literary training proper.

Again, whether used for this or for any purpose, it is useless unless it reaches a high standard. To reach such a standard is itself specialisation, and would require so much time that a boy would be unable to learn with any efficiency any other subject. That is to say, he would have to devote to the study as much time as those boys who enter for classical scholarships. Greek, be it understood, implies Latin. The abolition of Latin as well as of Greek is hardly dreamt of as yet.

Prof. Murray, who thinks that the vital point is "the maintenance of both Greek and Latin—but a better as well as an easier Greek and Latin," is assisted by the classical reformers. These are applying new systems, the most important of which is known as the Frankfurt scheme, for the production of better classical results in half the time. Thus, whereas in the old English public-school system a boy took about ten years to attain proficiency, but by no means adequate proficiency, in two dead languages which he never learned to speak, under the Frankfurt scheme, the first three years, say from nine to twelve, are chiefly devoted to obtaining a good grounding in French instead of in the acquisition of Greek and Latin grammar. Then, and not until then, is Latin commenced; Greek is commenced two years later.

On these lines a great deal of experiment is being made in English schools. Much ingenuity is also being shown in methods for quickening and improving the assimilation of Greek and Latin—the oral method, the heuristic, the principle of learning translation from the very beginning instead of after a long training in grammar, and so on. But it is noteworthy that towards the end of the course the classical time-table becomes excessive again.

It does not seem to have occurred to educationists that possibly the only way of learning a foreign language is by speaking it, and that the best results are obtained by learning the vernacular first. There is a further possibility awaiting realisation, namely, that the study of any other language than the vernacular is a case of specialisation. It follows that the imposition of Latin or Greek or French on the curriculum of young boys is at least premature. In time, lastly, we may come to realise that "no man fully capable of his own language ever masters another," or, at any rate, that for the purposes of a general preliminary education or propædæutic (as contrasted with specialisation), not only is the vernacular sufficient if properly taught, but that the learning of another language or languages while the vernacular is in process of formation is so far from being

an aid in this or an assistance to mental development that it is actually mischievous.

The traditionists (for, after all, tradition, whether of the old "learning" or, in more subtle form, of a sort of class prejudice, seems to be the main reason for the retention of classics as a propædæutic) reply that the character of the classical tongues, their inflectional structure and their logical habit, are of great value in the development of the intellect. Instead of asking for proofs of this, we may note the possibility that an efficient study of the vernacular can secure the same results. The Germans (as is shown in a recent report¹) are beginning to see this. The classicists may quote anecdotes of this or that distinguished man who attributed his lucid and logical English style to his early training in Latin prose, but the same or a better result could be secured in far less time. If the time now given in our schools to classical and modern languages were given to English, the benefits would be enormous both for the general culture of the people and for the special work of specialists, whether in science or languages, in "technical" or "literary" studies. The English taught in schools as yet is a mere parody of what it might be. It is remarkable that the English language does not possess a single text-book of its natural history that can claim any philosophic or scientific importance.

If English were properly taught as the main component of a propædæutic (the other components being elementary mathematics and science, the study of which also needs reorganisation), boys who begin specialisation (for specialisation now perforce begins at school), whether in science or mathematics, would find "literary" studies by no means an obstacle. They would have a command of their own language far in advance of the best classical or "literary" scholar as trained to-day. The result would also be a great benefit to science itself.

The world has already absorbed the Greek "spirit," but it should not forget the fact that the essence of that spirit is the scientific temper. It must also realise that as knowledge increases in bulk there must be periodic sacrifices of what can best be spared. "The wisdom of the ancients" is a phrase which, if not merely sentimental, is absurd. *Antiquitas saeculi juvenus mundi*.

Reform is needed in the school curriculum no less than in the university system. If the propædæutic there is on sound principles, there will be no fear of scientific students being without a literary training (and this in the best and most useful direction, the mother-tongue), nor, we may add, will there be any risk of "literary" students being without a scientific training. Greek and Latin will then be reserved for special university courses, just as Hebrew, or rigid dynamics, or forestry may be so reserved, according as the specialist is moved by his own spirit or the spirit of evolution.

A. E. CRAWLEY.

THE CENSUS OF 1911.

THE Census (Great Britain) Bill, making provision for the taking of the census of 1911, was read a first time in the House of Commons on March 4. The Act for the last census, that of 1901, provided that the schedule should require the following particulars, and no others:—"(a) the name, sex, age, profession or occupation, condition as to marriage, relation to head of family, birthplace, and (where the

person was born abroad) nationality of every living person who abode in every house on the night of the census day; and (b) whether any person who so abode was blind or deaf and dumb, or imbecile or lunatic; and (c) where the occupier is in occupation of less than five rooms, the number of rooms occupied by him; and (d) in the case of Wales or the county of Monmouth, whether any person who so abode (being of three years of age or upwards) speaks English only or Welsh only, or both English and Welsh"—a provision suitably modified in the case of Scotland by a reference to the speaking of Gaelic instead of Welsh.

These requirements have been amplified in the Bill now before Parliament by omitting the limitation to "less than five rooms" in (c), so that all occupiers will have to make a return as to the number of rooms inhabited, and by the addition of a new section:—"In the case of any person who so abode being married, the duration of marriage, and the number of children born of the marriage." The first change is of importance, as it will enable the census authorities to give tables covering, more completely than was formerly the case, tenements inhabited by the working classes, and it may be hoped that, in the subsequent tabulation, some distinction as to the ages of persons inhabiting tenements of each given size may be found feasible; a distinction between children and adults would render possible some better indication of overcrowding than the present somewhat crude measure of "more than two persons to a room."

The new section requiring a return, in the case of married persons, as to the duration of marriage and the number of children born of the marriage is of the very highest interest, though its full value will not be reached until the results of later censuses are available for comparison. If the returns are tabulated so as to show the number of children for a given age of mother and a given duration of marriage, it will be possible to compare essentially similar marriages in different districts, and some fresh light will be thrown on the present state of legitimate fertility in this country. It is also to be hoped that a subdivision may be found possible according to the occupation of the father; it would be sufficient to choose a few typical groups of occupations, and it would hardly be necessary to do more than give tables for England and Wales as a whole. Such tables would afford information of the most important kind, which we do not at present possess in any form.

No question is included as to religion, except in the case of the Irish census, for which separate provision is made, and the present Census Bill is very disappointing in that it makes no attempt to place the organisation of the census on a permanent basis or to provide for an intermediate quinquennial census. It is absurd that so important a part of the stock-taking of the nation, as the census is, should be dependent on the chances of party politics, and it is false economy to spend time and money on training a staff for the execution of census work and then to scatter that staff to the four winds—only to go through the process again after a few years have elapsed. A smaller but more permanent staff would be much more efficient and could be fully engaged between one census and the next in the carrying out of supplementary investigations after the publication of the main report. The necessity for the intermediate quinquennial census has been shown again and again, but the statement of the President of the Local Government Board that he is "not without hope that a system of quinquennial census may come to be adopted" cannot be said to carry conviction.

¹ "The Teaching of Classics in Secondary Schools in Germany." (Board of Education Special Reports, vol. xx., 1910.)

ALEXANDER AGASSIZ, FORMER MEM. R. S.

ALTHOUGH the great American oceanographer had reached the age of seventy-five, few of his friends were prepared to hear of his death, which appears to have taken place, somewhat suddenly, on board the s.s. *Adriatic* on March 28, while on a voyage back to the United States.

The distinguished son of a famous father, Alexander Agassiz was born in Switzerland but naturalised in America; yet, so cosmopolitan was he in his tastes and habits, that if ever an individual deserved the title of "a citizen of the world" he was the man. Up to the age of thirteen, he was educated in his native land, but, proceeding to the United States in 1848, he went to the Harvard University, where—as a student in chemistry and engineering—he obtained his degree of B.Sc. at the age of twenty-two. After spending a short time as a member of the United States Geological Survey, young Agassiz became a mining expert, and so successful was he in this profession that, acquiring possession of valuable properties in the Lake Superior region, he rapidly made a very large fortune in connection with the copper mines.

The love of natural-history studies, however, which he inherited from his father, soon made itself felt; at first he assisted his father as curator of the Museum of Comparative Zoology at Harvard. As his wealth increased, he was able to benefit that institution, not only by specimens collected during his extensive travels and by defraying the cost of many expensive publications, but also by gifts of money up to 100,000. After the death of his father he acted as curator of the museum for eleven years. Beginning with the study of marine ichthyology, he subsequently came to be acknowledged as a great authority on the Echinodermata, so that, on the return of the *Challenger* expedition, he was asked to undertake his report on the Echini collected during the voyage.

But the work for which Alexander Agassiz will be chiefly remembered was that which, during nearly forty years, he carried on at his own expense in connection with oceanography. The United States Government, with the greatest liberality and consideration for the interests of science, allowed him from time to time the use of their surveying vessels, the captains of which were instructed to place themselves virtually under the orders of Agassiz himself. The naturalist, aided by a staff selected and paid by himself, carried on soundings and dredgings in every part of the globe, special attention being devoted to the study of coral reefs. Beginning, in 1877, with the study of the Gulf of Mexico, the Caribbean Sea, and the Atlantic coast of America, Agassiz continued his work in 1880 by investigating the surface fauna of the Gulf Stream. Besides working out the details derived from the study of collections made during these voyages, the results of which were published in connection with the Harvard Museum of Comparative Zoology, Agassiz wrote a well-illustrated account of his work, "The Three Voyages of the *Blake*," in two volumes.

In 1891 Agassiz transferred his attention to the western shores of the United States and Central America, investigating the seas around the Sandwich Islands, and paying special attention to the coral reefs here, between 1892 and 1894. His explorations were extended during 1895-6 to the Great Barrier Reef of Australia, and in 1897-8 to the Fiji Islands. In 1899 and 1900 he was able to undertake a cruise among the various groups of coral-islands lying between San Francisco and Japan. In 1901-2 Agassiz commenced

his study of the Indian Ocean, paying especial attention to the Maldive Islands and their surroundings; and, in order to complete the examination of portions of the Pacific that he had not already visited, he devoted the years 1904-5 to a cruise among the important island-groups of the eastern half of the Pacific Ocean.

The intervals between his several voyages were occupied by Agassiz in the study of his enormous collections and the preparation of memoirs dealing with the results obtained. These were issued, regardless of expense as to their illustration, in the publications of the Boston Society's Museum of Comparative Zoology. No fewer than thirty volumes of memoirs and fifty-three volumes of bulletins are devoted to the results obtained from the study of these collections by Agassiz and the various specialists who assisted him. His own favourite place of work was Paris, where rooms were always allotted to him in the Museum of Natural History, and he had the fullest access to scientific libraries.

Of the value and importance of the results of these voyages it is impossible to speak too highly. Perhaps the most striking of the conclusions arrived at by him are those relating to great movements which have taken place in the bed of the Pacific in comparatively recent geological times. This is evidenced by the numerous upraised coral-reefs which, following Dana, he described; in many of these the limestone rock, now at elevations of 1000 feet and upwards, has been more or less completely converted into dolomite.

It is not necessary, in face of the above statement of facts, to add that Agassiz was a man of indomitable energy. He thought as little of crossing the Atlantic as we do of crossing the Thames, and death met him at last while still "on the move." Of his courage, a remarkable example is told concerning an altercation he had with a military officer in a crowded restaurant in Germany; on that occasion he did not hesitate to resent an insult by a blow, though fortunately any serious result from the rash act was prevented by the interposition of a number of judicious friends of the officer, aided by American and English visitors who were present. In early life, Alexander Agassiz exhibited something of the dogmatic habit of mind that distinguished his illustrious father; but, mellowed by age and constant intercourse with other men, he became in after life strikingly open-minded and ready to listen to arguments, even those that told against his most cherished convictions. Those who were privileged to enjoy his friendship in his later life knew him as a man of ardent enthusiasm, restless energy, and charming bonhomie, but also as one patient in discussion, and always ready to listen to facts and reasonings from whatever quarter they came. His generosity was unbounded, and he was always ready to place his abundant materials at the service of young men who were qualified and willing to engage in their study.

In every scientific circle of Europe, as well as in those of America, Alexander Agassiz was well known, and in all of them his loss will be deeply mourned. In France he received the Légion d'Honneur, and in Germany the Order of Merit. In this country he was for many years a Foreign Member of the Royal Society. Only last year the Royal Geographical Society awarded him the Victoria research medal, and we may fitly conclude this notice with the verdict of the president in announcing the award—a verdict in the justice of which all must agree—"He has done more for oceanographical research than any other single individual."

JOHN W. JUDD.

NOTES.

THE Oceanographical Museum at Monaco was inaugurated last week by the Prince of Monaco in the presence of a gathering of more than two hundred representatives of Governments, of scientific institutions, and of oceanographical research. Among many others present were:—M. Loubet, ex-President of the French Republic; M. Pichon, French Minister of Foreign Affairs; Admirals of the Fleet von Koester from Germany and Grenet from Italy; Vice-Admiral de Jonquières, commanding the French Mediterranean Squadron; and distinguished representatives of the Governments of Spain and Portugal. The Institute of France sent a large body of members representing the Academies of Sciences and of Fine Arts. The Academy of the Lincei at Rome, the Academies of Sciences at Berlin, Vienna, and St. Petersburg, the Royal Societies of London and Edinburgh, the Geographical Societies of Paris, Berlin, Vienna, and St. Petersburg, the Challenger Society, and many other societies and institutions were amongst the societies sending delegates. The British Government was not represented officially, owing to some blunder, but Mr. W. E. Archer, of the Board of Agriculture and Fisheries, Mr. J. Y. Buchanan, F.R.S., Dr. G. H. Fowler, Prof. W. A. Herdman, F.R.S., Dr. J. Scott Keltie, and Dr. H. R. Mill represented British marine studies. Among the leading men connected with oceanography, marine biology, and kindred sciences in other countries there were Mr. Bendall, of Bordeaux; Prof. Drygalski, of Munich; Prof. Forel, of Lausanne; Senator Grassi, of Rome; Prof. Haeckel, of Jena; Dr. P. P. C. Hoek, of Haarlem; Prof. Hensen, of Kiel; Prof. Hergesell, of Strassburg; Dr. Knipovitch, of St. Petersburg; Prof. Krümmel, of Kiel; M. de Margerie, of Paris; Prof. Otto Nordenskjöld, of Gothenburg; Prof. Penck, of Berlin; Prof. Perrier, of Paris; Prof. Pettersson, of Stockholm; Dr. Schmidt, of Copenhagen; Dr. Schott, of Hamburg; Prof. Supan, of Breslau; Prof. Thoulet, of Nancy; Prof. Max Weber, of Amsterdam; and Dr. Richard, director of the new museum, with Profs. Berget, Joubin, and Portier, of the Oceanographical Institute in Paris. The museum was inaugurated by the Prince of Monaco at a grand function on Tuesday, March 29; on the following day there was a banquet to three hundred guests, and the evenings were occupied by a special performance at the famous Opera House in Monte Carlo, a display of fireworks of extraordinary brilliance in the harbour, and finally by a magnificent State reception in the gorgeous apartments of the ancient palace of the Grimaldis. Meetings of four commissions, on the Atlantic, on the Mediterranean, on the perfecting of the Oceanographical Institute, and on the bathymetrical chart of the world, were held under the presidency of the Prince, and a summary of the proceedings will appear in another issue of NATURE. The Prince conferred the Order of St. Charles in four classes on a number of persons, amongst whom may be mentioned as receiving that of the second class, or commander, Mr. J. Y. Buchanan, Senator Grassi, Prof. Penck, and Dr. Richard. The princely hospitality displayed on the occasions extended to the provision of free hotel accommodation for all the visitors invited to the fêtes, while the representatives of States were entertained at the Palace as personal guests of the Prince.

SIR WILLIAM RAMSAY, K.C.B., F.R.S., has been nominated president of the British Association for the meeting to be held at Portsmouth next year.

SIR HARRY JOHNSTON, G.C.M.G., has been elected a corresponding member of the Italian Geographical Society, in recognition of his work in Africa.

NO. 2110, VOL. 83]

WE regret to see the announcement of the death, at eighty years of age, of Prof. E. Pflüger, professor of physiology at the University of Bonn, and director of the Physiological Institute there.

THE council of the Institute of Metals has decided to initiate what is hoped will be an annual series of May lectures. The first of these will be given in London on Tuesday, May 24, when Prof. W. Gowland, F.R.S., will deliver a lecture on "The Art of Working Metals in Japan."

A REPORT from Berlin states that Prof. Abegg, of the University of Breslau; was killed as the result of a balloon accident on April 3. Prof. Abegg was president of the Silesian Aeronautic Society, and a prominent figure in the German aeronautic world.

WE learn from the *Chemist and Druggist* that M. Henry Giffard, who died at Paris in 1882, made the State his residuary legatee. By a recent decree the Minister of Public Instruction placed a sum of 4000l., being part of the legacy, at the disposal of the University of Paris for the foundation of an Institute of Radio-activity.

AT to-morrow's meeting of the Royal Astronomical Society, Prof. P. Lowell is expected to be present, and will speak upon his work. Major-General H. P. Babbage will exhibit and describe a calculating machine which he has recently completed, corresponding to the portion of the analytical engine which his father, the late Charles Babbage, named "The Mill."

A REUTER telegram from Berlin states that an expedition will leave Bremerhaven on July 1 on board the North German-Lloyd steamer *Mainz* for Spitsbergen in order to investigate the possibilities of an airship flight to the North Pole, which is planned for the summer of 1912. The party will include Prince Henry of Prussia, Count Zeppelin, and Profs. Hergesell and Drygalski, and will number altogether twenty-four members.

THE valuable collection of shells formed by the late Mr. Thomas Gray, a well-known Glasgow conchologist, who died recently at the advanced age of eighty-nine, has been left by him to Kelvingrove Museum, Glasgow. More than 7000 species of shells are represented in the collection, including both British and foreign, land, fresh-water, and marine forms. It is said to be the finest collection of its kind in Scotland, and its possession places the Kelvingrove Museum well abreast of the leading museums in this country.

AN Industrial and Agricultural Exhibition will be held at Odessa from May 15 to October 1 of this year. During the exhibition there will be lectures on technical and scientific subjects, and arrangements are being made for some congresses. The cooperation of scientific men is invited by the committee of the exhibition (Odessa, Novoselskaja 4, Technische Gesellschaft).

THE Civil Service Commissioners announce that, in addition to the open competitive examination for situations as cartographer in the Hydrographic Department of the Admiralty, which is to be held in July next, another open competitive examination for similar situations will be held in December. Forms of application for admission to the December examination will be ready for issue about the middle of July, and will then be obtainable on request, by letter, addressed to the Secretary of the Civil Service Commission, London, W.

MR. F. G. OGILVIE, C.B., has been appointed by the President of the Board of Education to a new post of Secretary of the Board for the Science Museum, Geological Museum and Geological Survey. Mr. E. K. Chambers has been appointed to succeed him as principal assistant secretary of the technological branch of the Board. Dr. H. F. Heath, director of special inquiries and reports, has been appointed to the post of principal assistant secretary of the universities branch of the Board in combination with his present post.

MR. WALTER RUNCIMAN, President of the Board of Education, has appointed a departmental committee to consider and report upon various questions in regard to the present condition and the future development of the valuable collections comprised in the Board's Science Museum at South Kensington and Geological Museum in Jermyn Street. In particular, the committee is asked to advise him (a) as to the precise educational and other purposes which the collections can best serve in the national interests; (b) as to the lines on which the collections should be arranged and developed, and possibly modified, so as more effectively to fulfil these purposes; and (c) as to the special characteristics which should be possessed by the new buildings which it is hoped will be erected shortly on the South Kensington site to house these collections, so as to enable the latter to be classified and exhibited in the manner most fitted to accomplish the purposes they are intended to fulfil. The committee is as follows:—Sir Hugh Bell, Bart. (chairman), Dr. J. J. Dobbie, F.R.S., Sir Archibald Geikie, K.C.B., P.R.S., Dr. R. T. Glazebrook, F.R.S., Mr. Andrew Laing, Sir Schomburgk, F.R.S., Sir William Ramsay, K.C.B., F.R.S., Prof. W. Ripper, Sir W. H. White, K.C.B., F.R.S., with Mr. F. G. Ogilvie, C.B., as secretary.

REUTER messages from Catania record that the eruption of Mount Etna increased in violence up to the end of March, when a stream of lava was moving at a speed of nearly forty yards an hour in the direction of Cisterna Regina, near Borrello. On April 4, however, the activity had considerably lessened. The streams of lava had diminished in volume, and changed their direction. They were then flowing towards Monte Rinazzi and Monte Aggi, submerging the lava remaining from previous eruptions. There was a pronounced recrudescence of the eruption early on April 5. The lava stream flowing towards Cisterna Regina in particular increased its rate of progress to 10 metres an hour, and reached a spot only 50 metres distant from the Nicolosi Borello road, destroying the cultivated land on its course.

THE summary of the weather for the first three months of the present year, just issued by the Meteorological Office, shows that the mean temperature was above the average over the entire kingdom. The rainfall was below the average in the north of Scotland, and in agreement with the average in the north-east of England, whilst in other districts the fall was in excess of the average; the greatest excess was 2.77 inches, in the north of Ireland. The largest total measurement was 14.61 inches, in the north of Scotland, and the least 5.21 inches, in the east of England. The number of rainy days were everywhere in excess of the average. There was an excess of sunshine over the whole of Great Britain, amounting to 10 hours in the Midland counties, 76 hours in the north-west of England, and 70 hours in the south-west of England. The largest aggregate duration of sunshine for the three months was 362 hours, in the Channel Islands,

and the least 212 hours, in the north of Ireland. There was an excess of sunshine in twelve out of thirteen weeks in the Midland counties, and in eleven out of thirteen weeks in the south-west of England.

MR. R. M. BARRINGTON, writing from Fassaroe, Bray, Co. Wicklow, says:—"On March 21, at 9 a.m., the reading of the wet-bulb mercurial thermometer 4 feet from the ground in a Stevenson's screen was 1° F. higher than the dry-bulb mercurial thermometer 3 inches distant in the same screen, the readings being 46° and 45° respectively. Assuming the instruments are accurate and in working order, can such a thing occur?" He adds that at the moment of observation the temperature was falling rapidly. A distinguished meteorologist informs us that cases of the wet bulb above the dry are by no means rare, but the difference is rarely so much as 1°. They are generally dealt with in practice by attributing the differences to instrumental errors or temporary meteorological circumstances (such as the rapid fall of temperature noted by Mr. Barrington), which bring out an imperfection in the conventional methods of thermometry.

THE tragedy which deprived M. Charlois of his life on Easter Day deprived French astronomy of a brilliant worker and the Nice Observatory of an enthusiastic observer. M. Charlois devoted himself chiefly to the minor planets, and was only second to Dr. Max Wolf in the number of these bodies which he discovered. At the foundation of the Nice Observatory by M. Bischoffsheim in 1881, Charlois was appointed secretary to M. Perrotin, the first director, and in 1887 was given charge of the minor planet work. Observing with the 38-cm. refractor he discovered, up to December, 1902, 104 which previously had escaped detection. Twenty-seven of these were found visually, between 1888 and 1892; but M. Charlois was the first to adopt Dr. Wolf's photographic method, and thereby added seventy-seven more asteroids to the rapidly growing family. These he discussed in vol. viii. of the *Annals of Nice Observatory*, but he also published a number of orbits, observations, &c., in the *Bulletin astronomique*, the *Astronomische Nachrichten*, &c.; for this work he was awarded the Janssen medal of the Astronomical Society of France in 1899. Minor planets did not, however, absorb all M. Charlois's energies, for he observed many comets, measured double stars, made a great number of latitude observations, and accompanied M. Thollon to Spain for the transit of Venus in 1882. At the transit of Mercury in 1907, he made observations which afforded corrections to the ephemeris, and he also rendered valuable assistance to the International Astrographic Conference in their work on Eros; it is interesting to note that he secured a plate showing the trail of this remarkable asteroid on the same evening that it was discovered by De Witt, but did not recognise it until after the announcement of the discovery by the Berlin observer.

LITTLE has hitherto been known of the language of the Yana tribe of Indians, who occupy part of Shasta County, in the northern region of California. This want has now been supplied by Messrs. E. Sapir and R. B. Dixon, who have contributed to the ninth volume of the *Publications of the University of California* a series of legends recorded from the lips of the two last survivors of those learned in the tribal traditions. One of these tales is a remarkable variant of the Prometheus type of legend, describing how Fox, Sandpiper, and Coyote stole the fire, how the world was burned, and how the thieves escaped in a basket which Spider hauled up to heaven by his thread. Another and less complete version of the tale has been published by Mr.

J. Curtin in his "Creation Myths of Primitive America." The present collection of tales, recorded in two dialects, will preserve for the use of philologists a language which is fated before long to disappear.

THE group Mesozoa is, as is well known, a kind of zoological waste-paper basket into which various obscure forms of extremely lowly organisation have been cast from time to time. Many of these forms are of great interest as indicating possible transitions from the unicellular to the multicellular condition. The genus *Haplozoon* has been added to this miscellaneous assemblage by Dr. Dogiel, who describes some new species thereof in the *Zeitschrift für wissenschaftliche Zoologie* (Band xciv., Heft 3). These remarkable parasites, which live in the alimentary canal of various polychæte worms, occur in the form of single or multiple chains of cells, the first cell of the series being provided with one or more stylets. Dr. Dogiel has proposed the group-name *Catenata* for these organisms, which he considers to be derived from the unicellular *Peridinea*, and to exhibit protophyte rather than protozoon affinities.

IN a paper on the stability of the physiological properties of coliform organisms (*Centralbl. f. Bakteriologie*, Abt. ii., Bd. 26, 1910, S. 161) Mr. Cecil Revis suggests that the capacity of a micro-organism to ferment various sugars, polyhydric alcohols, and polysaccharides depends on the presence of certain atomic groups in the substances. Thus glucose, mannose, galactose, lævulose, and lactose all contain the group —CHOH—O—CH= , and are fermented by *Bacillus coli*, while sucrose does not, and is not fermented by many strains of *B. coli*. Attempts were made to change the fermentive properties of various strains of *B. coli* and other organisms by prolonged sojourn in soils contaminated with fæces, &c., and in a non-albuminous medium. After some months changes were frequently noticed in the organisms isolated. Thus with one typical *B. coli* which fermented lactose, dulcitol and glucose well in twenty-four hours, after seven months in soil contaminated with human fæces an organism having the original properties was isolated, and, in addition, three other forms, A, B, and C, were isolated, characterised by differences in the appearance of their colonies. Of these, A and C gave the original reactions unchanged, but B fermented none of the test substances. Other instances of similar changes are given. In control cultures kept on gelatin, in general no change at all occurred.

THE Municipality of Hanover, according to a paper by Mr. E. Howarth on some German museums in the February number of the *Museums Journal*, deserves the gratitude of antiquarians for having restored and fitted up as a museum Leibnitz House, the picturesque fifteenth-century residence of a German merchant. It contains four storeys, all stocked with objects of industrial art and industry, arranged from an æsthetic rather than a systematic point of view.

IN the March number of the *Irish Naturalist* Mr. R. J. Ussher gives his experiences of cavern-exploration in Ireland, in which he has taken so large a share. Most important of all is the mammoth-cave near Doneraile, Cork, which was worked from 1904 onwards, and is older than any other except Shandon. This cavern takes its name from the number of mammoth-remains, but is also characterised by the abundance of reindeer and the absence of red deer, wild boar, and badger.

ACCORDING to the report of the Lancashire and Western Sea-fisheries (to which allusion was made in a recent issue), there is reason to believe that black-headed gulls are injurious to cockle-beds. In the Floodborough district

these birds have been ascertained to feed almost exclusively on young cockles, which they pick out of the sand. It is accordingly recommended that these birds should be excluded from the Wild Birds Protection Act, and their eggs destroyed in the breeding-season.

IN the course of an interesting account of his recent journey in north-western Arabia, published in the March number of the *Geographical Journal*, Mr. Douglas Carruthers claims to be the first European who has sighted the Arabian ostrich since Palgrave's time. Three were seen in the Wadi Hidrij, about 120 miles south-east of the Dead Sea, which is probably the northern limit of these birds, the range of which includes all the interior of Arabia. It is suggested that the Arabian ostrich is inseparable from the typical *Struthio camelus* of North Africa, but since the Arabian oryx and baboon are distinct from their African relatives, this is by no means certain, and can only be determined by the acquisition of actual specimens. Mr. Carruthers states that the interior of Arabia is undergoing secular desiccation, so that many of the Beduin find it increasingly difficult to maintain themselves.

THE question of the proper pose of the limbs of *Diplodocus*, which was opened some months ago by Dr. Hay, has been taken up again by Mr. G. Tornier in a paper published in the *Sitzber. Ges. naturfor. Berlin*, 1909, p. 193. In this paper a restoration is given of the skeleton, in which the shoulder-girdle is pushed low down and the humerus and femur are extended almost horizontally, so as to bring the belly within a very short distance of the ground, while the head and neck are raised aloft in swan-like fashion, the feet being mounted in wholly plantigrade style. The general appearance of the skeleton is somewhat grotesque. On p. 507 of the serial cited Mr. Tornier replies to those who have criticised his restoration of *Diplodocus*. Prof. O. Abel (*Verh. k.k. zool. bot. Ges., Wien*, 1909, p. 117) has likewise entered the lists, and urges that all the sauropod dinosaurs were "elephant-footed," that is to say, in place of being plantigrade, their feet were of the semi-digitigrade type characteristic of the Proboscidea, with posterior foot-pads. This Mr. Tornier refuses to admit in a paper published in the *Sitzber. Ges. naturfor., Berlin*, 1909, p. 537, where the completely plantigrade character of the feet of these reptiles is re-asserted.

MR. B. H. RANSOM, assistant-custodian of the helminthological collections, the National Museum of Washington, has written a valuable work on the tænioid cestodes of North American birds (*Bulletin No. 69, U.S. National Museum, Washington*, 1909). Ten years ago, when studying under Prof. H. B. Ward, at that time of Nebraska, he began an investigation into the cestodes of North American birds, and the present volume, of 140 pages, is the first outcome of this research. The volume contains detailed descriptions of five new species, and there are numerous adequate figures. It also contains keys to the genera of the superfamily Tænioidea, diagrams of families, subfamilies, and genera, and lists of the species occurring in North American birds are added. The recent monograph of Dr. O. Fuhrmann, the well-known authority on bird tape-worms, has been of great service to the author. Mr. Ransom's paper ends, as is usual with American publications, with a very full bibliography and an accurate and full index, for which we cannot be too grateful to the author.

DR. K. M. LEVANDER has published an important work on the food and parasites of fishes in the Gulf of Finland ("*Beobachtungen über die Nahrung und die Parasiten der Fische des Finnischen Meerbusens*," *Finnländische Hydro-*

graphisch-Biologische Untersuchungen, No. 5, Helsingfors, 1909), supplementary to the earlier works of Dr. G. Schneider. A work of this kind requires very careful analysis and abstracting, and if we are to learn which of the species forming the food has supplied the parasites in question, we must carry the research rather farther. We have in this work very long lists of species of insects and their larvæ, of Crustacea and their larvæ, of molluscs, occasional worms, and other fish all eaten as food. We have also considerable lists of cestodes, trematodes, nematodes, Acanthocephala, &c., but the paper does not, in our opinion, sufficiently attempt to indicate which food-animal brought into the body of the fish the several parasites enumerated. Nevertheless, the work forms a foundation for further investigation, and one which will afford material for a greatly developing subject.

THE spread of interest in ecological botany is naturally creating a demand for photographs and lantern-slides of typical areas of vegetation. Mr. W. B. Crump, of Halifax, who has taken part in some of the British botanical surveys, has accumulated a series of photographic negatives

of *Hevea brasiliensis*, received almost simultaneously from Singapore and the Gold Coast, receives the name of *Diplodia rapax* (Melanconiaceæ). Mr. A. D. Cotton contributes an article on the growth of the alga *Ulva latissima*, which, in contrast to most algæ, flourishes in stagnant and sewage-polluted water.

MESSRS. J. B. BAILLIÈRE ET FILS are issuing a small monthly booklet, *Le Mois agricole*, containing notes likely to be of value to the agriculturist, the vine-grower, and the gardener. There are also detailed notices of the recent publications of the firm.

THE necessity for continued work on the sugar-cane is thoroughly recognised in the West Indies, and bulletins are regularly issued setting forth the results obtained up to the time of publication. We have recently received Pamphlet No. 63 of the Imperial Department of Agriculture for the West Indies, giving a summary of the results obtained in Antigua and St. Kitts during 1908-9.

THE Agricultural and Horticultural Association issue an annual booklet entitled "One and All Gardening," containing a number of short articles of interest to gardeners and others. Among the most attractive is one by the Hon. H. A. Stanhope, in which the legends attached to certain plants are pleasantly re-told. The outdoor school lessons given at the Frensham Schools in Surrey are described, while Miss Sipe writes on school gardening in the United States. The booklet is well illustrated.

(b)

FROM the Edinburgh and East of Scotland College of Agriculture we have received a bulletin, by Dr. Lauder and Mr. Fagan, giving the milk records for the dairy herd at the Rosslynlee Asylum. An attempt was made to trace the relation between ventilation of the cow-sheds and the yield of milk, but the results are not very decisive. So far as they go, they indicate that the animals in the well-ventilated, and therefore colder shed, gave

at least as much milk as those in the warmer, ill-ventilated sheds, and remained in a healthier condition.

A REPORT has recently been issued by Mr. E. Brown on the poultry industry of 1909, from which it appears that the decline in the import of foreign eggs, which has been going on since 1903, still continues, not so much as a result of increased home production as of increased requirements by Germany, now the largest importer of poultry produce in the world; but although the amount of our imports has declined, the values have risen, and the factors at present controlling prices seem to be permanent. It is urged that farmers and small holders have now an opportunity in connection with poultry raising such as they never have had before.

IN vol. lii., part iv., of *Smithsonian Miscellaneous Collections*, Mr. G. P. Merrill describes and figures a stony meteorite which has recently come into the possession of the U.S. National Museum at Washington. The interest

Calluna Heath : a Cheshire Mere. (a) *Molinia coerulea*; (b) *Juncus supinus*.

depicting many of the recognised plant associations, from which he offers permanent photographic prints (15 by 12 inches or 12 by 10 inches) made by the ozobrome process or lantern-slides. Descriptive notes are supplied. The photograph reproduced represents a Cheshire mere, near the margin of which clumps of *Molinia coerulea* are growing, while heather is seen in the immediate foreground, and a plot of *Juncus supinus* occurs on the further side.

THE first issue of the *Kew Bulletin* (1910) opens with a descriptive list, communicated by Mr. G. Massee, of new rotic fungi. An agaric, *Marasmius scandens*, so called from the way it extends its cord-like mycelium and produces the resupinate pilei at intervals, is reported to cause considerable damage to cocoa plants on the Gold Coast. Two suspected insect parasites are described, viz. *Sclerotinia gigaspora*, taken on orange leaves with scale insects, and *Septocylindrium suspectum*, found on the bodies of dead frog-hoppers. A new parasite on the roots and branches

of this specimen, which is of rudely quadrangular form, with a maximum diameter of about $2\frac{1}{2}$ inches, consists in the fact that it was actually seen to fall by the late Mr. B. F. Wilson on October 15, 1888, in McDuffie County, Georgia. It fell within a distance of about thirty yards of the observer, who was engaged at the time in picking cotton, and was at first under the impression that someone had thrown a stone at him. The meteorite buried itself to a depth of some 6 or 8 inches in the soil.

An application of the hydrodynamical theory of seiches to the Lake of Garda (Benaco) forms the subject of an essay by Dr. Francesco Vercelli (*Memorie del R. Istituto Lombardo*, vols. xxi.-xxii. [3], 1). The form of the lake is very irregular, the lower end being divided into two branches by a rock forming the peninsula of Sirmione, and projecting for a considerable distance further under water. The author has calculated the positions of the various nodes, and has applied Chrystal's so-called "quartic approximation" to determine the periods of the various oscillations. On comparing these with limnographical observations made at Desenzano, a good agreement has been obtained, while the formulæ of Merian and of Du Boys are stated not to have led to the same satisfactory conclusions.

THE ordinary form of liquid bath for the determination of melting points has been modified by the introduction of an air-bubble system, causing a rapid circulation of the liquid, and hence a uniform temperature. The same idea has been very ingeniously applied by Mr. H. Stoltzenberg (*Zeitschrift für physikalische Chemie*, March 11) in designing a low-temperature cooling bath. The liquid (pentane) is caused to circulate by means of hydrogen bubbles through a spiral dipped in liquid air, ether, and solid carbon dioxide, or a mixture of ice and salt, according to the temperature required, and then passes into the vacuum-jacketted vessel in which the measurements are carried out. The temperature can be easily regulated by altering the amount of the spiral immersed, and can be kept very constant.

In the *Annalen der Physik*, iv., 30 (1909), Dr. M. Laue discusses the question of thermodynamic reversibility as applied to diffraction of light through a grating. The question has assumed a new aspect since the investigation of the properties of coherent pencils has shown that regular reflection and refraction at the surface of two media is not essentially irreversible. The conclusions at which Dr. Laue arrives are fairly simple and straightforward. If an indefinitely extended train of plane light waves falls on an equally indefinitely extended grating no irreversible change takes place. On the other hand, if the grating is limited in extent the measure of the irreversible changes, in terms of entropy, is equivalent to that produced by diffraction through an aperture equal in size to the grating itself. Thus the larger the area of the grating the less entropy change is associated with the diffraction, and every intermediate condition exists between the practically reversible diffraction of a very large pencil of light and the irreversible diffraction of a small one. In the *Physikalische Zeitschrift*, x., pp. 807-10 (1909), Dr. Laue enunciates analogous conclusions. He finds that the scattering of light by small transparent particles is irreversible, and that if diffraction at a grating is accompanied by absorption the change of entropy is the same as if the absorption were associated with an equivalent geometro-optical process. We have here a simple illustration of the utility of formulating a thermodynamical scheme on the dQ/T definition of entropy.

At the same time, the principle of coherence does not render it possible to produce an increase of available energy, but only to rescue what would otherwise be lost, and this is not inconsistent with a broader enunciation of the laws of thermodynamics.

MESSRS. G. PHILIP AND SON, LTD., have issued a planisphere of the earth (price 7s. 6d. net), devised by Mr. G. Morell, by which it is possible to determine, with a single adjustment, the local time corresponding to any given Greenwich time, or *vice versa*. The whole surface of our globe is projected upon a disc about 23 inches in diameter, capable of rotation about a point fixed at the North Pole. Parts of this disc show through a circular window about 13 inches in diameter on the face of the planisphere, and around this window the hour lines are marked, so that the relation between the meridians on the map of the earth and the time can be seen at once. About three years ago the same publishers produced a "Standard Time-dial," in which the north and south hemispheres of the earth were mounted back to back and rotated together on a single pivot (see *NATURE*, October 31, 1907). The planisphere now issued serves the same purpose, and while it has the advantage of enabling the relation between the times of any parts of the world to be seen at a single glance, it suffers from the disadvantage of great distortion in the case of regions south of the equator. For the consideration of relative times this distortion does not matter, though it would be misleading if used for purposes of geographical instruction, and it enables believers in a flat earth to show that all the phenomena of local time can be explained on their theory. The diagrams of constellations inserted around the circular opening convey a completely wrong impression as to the relation of the stars to the earth, but while the planisphere will be of little value educationally, it provides a very convenient means of determining easily the corresponding standard times at any instant in different parts of the earth.

THE first edition of Prof. J. Percival's "Agricultural Botany" was published by Messrs. Duckworth and Co. ten years ago, and was favourably reviewed in these columns (vol. lxii., p. 570). The work has been accepted as the standard text-book for agricultural students and others concerned with practical aspects of botany, and we are glad to welcome the appearance of the fourth edition. A new chapter has been added on the Linaceæ, with particular reference to flax or linseed; and among the additions is an account of Mendelian laws of inheritance, to which much experimental work has been devoted since the original volume appeared in 1900. The book now contains about twenty more pages than the first edition, and the revision and additions will enable it to maintain the high position it holds among text-books for the study of laboratory, and the reference book-shelf.

A COMPREHENSIVE catalogue of important works on mathematics, astronomy, physics, chemistry, and kindred subjects is comprised in the first part, just issued, of the supplement to Messrs. H. Sotheran and Co.'s "Bibliotheca Chemico-Mathematica." The notes to many of the works are both interesting and curious, and they make this catalogue a readable publication instead of merely a list of titles of books.

MESSRS. WATTS AND CO. have issued for the Rationalist Press Association, Ltd., a cheap reprint of Prof. Hæckel's "Last Words on Evolution." The price of the new edition is sixpence in paper covers and one shilling bound in cloth.

OUR ASTRONOMICAL COLUMN.

OCULTATION OF MARS, APRIL 13.—An occultation of Mars by the moon will take place at 10.28 p.m. on April 13, the planet disappearing behind the dark limb of the moon in position-angle 0° . Emersion will take place at 11h. 4m. p.m. in position-angle 278° , the angle in each case being reckoned from the zenith point of the moon towards the east.

COMET 1910A AND HALLEY'S COMET.—From an article by Mr. Knox Shaw, published in No. 40 of the *Cairo Scientific Journal*, we learn that photographs of comet 1910a were secured at the Helwan Observatory. The comet was first seen ten minutes after sunset on January 20, clouds having prevented earlier observations. The Reynolds reflector was not ready for photographing objects at such low altitudes, but some good photographs were secured with a 4-inch Cooke lens on January 24, 25, 27, and 28; more cloudy weather then intervened. The photographs show the twin tails and also the southern secondary tail, which is much fainter, and can only be traced to a distance of $40'$ from the head.

Mr. Shaw also publishes a useful diagram of the path of Halley's comet, with regard to the sun and the earth, during the period February 1 to May 29. A photograph of this object, obtained at Helwan on January 28, showed faint traces of a tail about $18'$ in length.

Three excellent photographs of 1910a, and one of Halley's comet, appear in No. 1, vol. iv., of the *Journal of the Royal Astronomical Society (Canada)*. They were taken at the Dominion Observatory, Ottawa, on January 25, 28, 31, and February 10, respectively. On the last-named date the negative of Halley's comet showed a tail 2° long.

A brief message from M. Jean Mascart informs us that he is at Tenerife, where, at an altitude of 2700 metres, he intends making observations of Halley's comet. M. Mascart's station is very near that occupied by Piazzi Smith during his sojourn, for astronomical observations, in the island.

SUN-SPOTS AND FACULÆ IN 1909.—Prof. Ricco's usual annual summary of the sun-spots and faculæ observed at Catania during 1909 appears in the February number of the *Memorie di Astrofisica ed Astronomia* of the Società degli Spettroscopisti Italiani (vol. xxxix., p. 17). On the whole, the activity displayed during 1909 was markedly less than that of 1908. In April, 1909, there was a sudden decrease of spots, the mean frequency becoming 2.5 instead of 4.1 as it was in March. This low value continued for six months, but in October there was a renewal of activity, the mean frequency again rising to 4.3, a value which it maintained until the end of the year. Thus, although the quarterly values of the frequencies were 4.1, 2.4, 2.3, and 4.3 respectively, the half-yearly values were more nearly equal, at 3.1 and 3.2, the latter also being given as the mean frequency for the whole year. The frequency values for faculæ vary in the inverse to those of spots, the quarterly values being 1.2, 1.4, 2.1, and 1.2; the mean for the year is 1.6.

THE NATURE OF COMETS' TAILS.—In the course of an article on the present position of the problem of the formation and constitution of comets' tails, which appears in the *Physikalische Zeitschrift* for March 15, Dr. L. Zehnder revives and extends a theory he first put forward twenty-six years ago in the pages of *Kosmos*. According to this theory, as the swarm of meteorites which constitutes a comet approaches the sun, the meteorites nearer the sun begin to give out gases and vapours which arrange themselves as atmospheres about single or about groups of several meteorites. These atmospheres refract the light from the sun, and, according to their densities, concentrate the sun's rays to foci at different distances behind themselves. If a meteorite is present at a focus it may be rendered visible, or even be heated sufficiently to produce combustion of any hydrocarbons present in it. The meteorites thus heated surround themselves in turn with atmospheres which concentrate the sun's rays on still more remote meteorites, and the visible tail of a comet is, according to the theory, the locus of the successive foci. Dr. Zehnder considers the forms of the refracting atmospheres which would produce the various types of tails now known.

PERIODIC ERRORS IN RIGHT ASCENSION OF STANDARD STAR CATALOGUES.—A comparison of the periodic errors of the right ascensions of the Newcomb, Auwers, and Boss standard catalogues is published by Dr. Downing in No. 420 of the *Observatory*. The comparisons were made with the "Standard Mean Right Ascensions of Clock Stars for 1900-0, based on Twelve-hour Groups," published in the Greenwich "Second Nine-year Catalogue," the places there given being, presumably, free from periodic errors depending upon right ascension.

The differences found are very small in amount, but most interesting in their distribution. There is a distinct drop at R.A. 4h. and a rise at R.A. 20h. which are too persistent, throughout the catalogues, to be entirely due to accidental errors. It is suggested that the peculiar distribution of magnitude through R.A. may account for some of, but not all, the discordances in question.

OBSERVATIONS OF SOUTHERN DOUBLE STARS.—The first number of the Circular of the Transvaal Observatory is devoted to the measures of a number of double stars discovered by Mr. Innes, with the 9-inch Grubb refractor, south of declination -19° . Experience shows that this instrument, used at the altitude (5900 feet) of the Transvaal Observatory, is capable of resolving very close doubles ($0.3''$) discovered by Prof. Hussey with the 36-inch refractor at Lick, and 11 per cent. of the 268 stars (Innes, 433-700) now given are separated by not more than $0.5''$; 43 per cent. have distances of $1.0''$ or less. Mr. Innes also gives a list of stars which have been wrongly identified by other observers.

THE "GAZETTE ASTRONOMIQUE."—We regret to learn from the current number of the *Gazette Astronomique*, published by the Antwerp Astronomical Society, that, until further financial support is forthcoming, this very useful journal for amateur astronomers will only be published alternate months, instead of monthly, as heretofore. The *Gazette* always contains ephemerides, notices of phenomena, &c., in addition to interesting accounts of observations; the subscription is 3 francs per annum, post free.

AURORAL DISPLAYS.

BRILLIANT displays of aurora were reported from many different parts of Scotland on the nights of March 27, 28, and 29, and aurora was also observed in Ireland and the northern portion of England. At Aberdeen aurora was seen each night between 8 and 9 o'clock. The *Westminster Gazette* gives an account of a brilliant display seen at Edinburgh early on the morning of March 28, stating that two separate displays were seen before 2 a.m., and there was a third shortly before 2.30 a.m. One of the first indications of the coming of this third display was a long, luminous shaft stretching upwards and intersecting the constellation Cassiopeia at a point near the star δ Cassiopeia. For some seconds it remained motionless and alone, like the tail of a great comet. Then the sudden flashing forth of a myriad quivering shafts and sheaves of light, exquisitely and delicately tinted, outlined a wide arch of striking beauty.

Mr. Wilfred C. Parkinson, writing from Eskdalemuir Observatory, Scotland, gives the following interesting details of the display on March 28:—

8.10 p.m.—Luminous band first observed in N. rising slowly like a bank of light cloud.

8.14-8.38.—Gradually assuming a curved form 10° - 12° above horizon at middle point, which was rather to the W. of N., and about 8° in width. Length about 140° .

8.40.—Band very bright and well defined, very intense at top edge, gradually thinning out towards the lower edge.

8.53.—The lower edge of the main band had formed a distinct band by itself, running parallel to the higher band, but not so wide, long, or intense. Higher band of uniform intensity throughout.

8.54.—Vertical streamer gradually forming, and also smaller ones, fluctuating in length and brilliancy.

8.56.—Vertical streamer very intense, especially where the curved bands cross it.

8.59.—Lower horizontal band gradually disappearing. Upper band growing faint and ill-defined. Vertical streamers growing more numerous.

(A most marked feature after 9h. was the way in which the streamers formed in the north and moved in a procession towards the west.)

9.8.—Lower band entirely gone. Upper band still visible, but faint. Numerous vertical streamers forming and intersecting the horizontal band.

9.16.—Horizontal band had entirely disappeared. Vertical streamers had increased in numbers and intensity. Constant fluctuations in brilliancy until 9.28, when last streamer had disappeared.

Mr. S. L. Elborne, writing from Peterborough, reports that on March 28, about 6 p.m., he saw a magnificent display of parhelia or mock suns, lasting about twenty minutes; on each side of the sun, and at equal distances from it in the same straight line, and parallel with the horizon, appeared a brilliant spot displaying the colours of the spectrum in the centre of each, giving the effect of three suns setting simultaneously; from each arose a luminous band, thus making a splendid arch over the true sun.

THE PUBLIC HEALTH OF THE METROPOLIS.¹

THIS report abounds in information of great interest to all who have at heart the well-being of the metropolis. The first part relates almost exclusively to vital statistics, the second to public health administration, and the third part contains much instructive matter upon school hygiene.

The year 1908 was a very exceptional one for London so far as vital statistics are concerned, for the marriage-rate (15.9), birth-rate (25.2), and death-rate (13.8) were the lowest ever recorded. The death-rate has shown a decline for the past forty years, while in the case of the birth-rate the fall year by year has been slight, but uninterrupted, for some thirty years. What this decline in the death-rate of a population of 4,795,757 persons implies is very forcibly expressed in terms of "life capital." By this expression is implied the years of life saved to the community by a reduction in the death-rate. The number of lives saved at each age period (as calculated by comparing the number of deaths for the year, in each age period, with the mean death-rates for those age periods for ten years, and crediting each life saved with the years representing the expectation of life at that age) represented a saving of 26,205 lives, and a gain to the community of 1,066,770 years of "life capital." The highest corrected death-rates were furnished by the City of London, Finsbury, and Bermondsey, and the lowest by Hampstead and Lewisham.

The infant mortality rate was lower in London for the last decennium than in all save one of the thirteen other large English towns; and London had a lower figure for 1908 than any of those towns. This fact, as Sir Shirley Murphy, the Medical Officer of Health, states, is matter for congratulation, though, as he adds, it needs to be remembered that the infant mortality rate is liable to considerable fluctuation, owing to climatic conditions and varying degrees of prevalence of epidemic maladies. There are notable differences in the rates of infant mortality in districts well and badly circumstanced socially, a fact which sufficiently indicates the results which might be obtained if the infants of the less favoured districts had extended to them the same care as that bestowed upon infants of the better favoured districts. Among metropolitan boroughs the loss of infant life has for several years been greatest in Shoreditch and Bermondsey, and least in Hampstead.

The infant mortality rate is, of course, affected by the administrative efforts made to reduce it, but the rate is so extremely sensitive to other influences, which vary from year to year, that the value of this work cannot be judged by the mortality of the moment. Among systematic efforts now being made in the metropolis for the preservation of infant life, Sir Shirley Murphy commends the system of visitation by health visitors, and he points out that the Notification of Births Act, 1907, which is such a valuable measure for enabling this work to be undertaken most

advantageously, had in 1908 been adopted in all but eight boroughs. In some districts official workers were supplemented by a staff of voluntary workers supplied by local health societies.

During the year 1908 the lowest death-rate from the epidemic diseases was recorded. No death occurred from small-pox, and the deaths from measles, whooping-cough, diphtheria, enteric fever, diarrhoea, and phthisis were below the averages of the last ten years, but those from influenza and scarlet fever were above the averages.

The London vaccination returns give food for thought and apprehension. As legislation has made it more and more easy to obtain exemption from vaccination, the unvaccinated children would be expected to increase. The latest returns recorded are those for the year 1906, when the percentage of unvaccinated children was 21.2, as against 26.4 in 1896, 7.8 in 1886, and 6.5 in 1876. There can be little doubt that the percentage of exemptions for the past three years will, when these are available, demonstrate a considerable increase. A notable feature in the behaviour of enteric fever in London in recent years has been the manifestation of localised prevalence occurring in poor populations and lasting often for a considerable number of weeks. There were two such prevalences in 1908, one in Bethnal Green and the other in Shoreditch, and Dr. Hamer furnishes, in an appendix, a full report on these two outbreaks.

Special reference is made to results obtained by Dr. Sidney Davies from the voluntary notification of zymotic diarrhoea among infants in Woolwich in the months of July, August, and September. Dr. Davies is of opinion that the infection spreads from person to person, and he thinks the distribution of the cases is consistent with the hypothesis that the disease is conveyed by flies. An examination of the statistics contained in his inquiry shows that while infants who are breast-fed suffered much less than those artificially fed, there is not much difference between the incidence of attack on children fed on cow's milk and those fed on condensed milk—except among the children fed on cow's milk at the Infants' Milk Depot, who suffered much less than other infants artificially fed.

The phthisis death-rate for 1908 was the lowest ever recorded. It amounted to 1.32 deaths to every 1000 persons living during the year. In dealing with phthisis the Medical Officer comments upon the work done in connection with the voluntary notification system in operation in twenty-one London boroughs in 1908, and he refers to the Order of the Local Government Board requiring notification of cases of phthisis in London which occur in Poor Law practice. London is, however, as the medical officer points out, but very imperfectly provided with the opportunities which are needed for utilising the knowledge thus gained. Phthisis mortality occurs especially among the poor, and measures for its reduction must not only include sanatoria and hospitals, but also those which afford assistance not only to the sufferer, but often to the families which are dependent upon him. It is here that the extension of philanthropic effort is greatly needed.

For the purpose of enabling the incidence of cancer on the several populations of the London sanitary areas to be more precisely stated, factors have been calculated for correcting the death-rates, so far as possible, for the differences in the age and sex constitution of the several populations compared. When these allowances are made it is found that in the year 1908 St. Pancras (1.17) had the highest rate, and that the lowest obtained in Fulham (0.79).

The question of nuisance from flies in connection with deposits of house refuse and stable manure has again been dealt with on lines similar to those followed in 1907, and the observations form the subject of another appendix to the report. In 1907, as in 1908, the large part played by collections of horse manure in determining fly prevalence was abundantly apparent, and the need for regulating the sanitary condition of stables was thus again emphasised.

On July 1, 1908, the administration of the General Powers Act, 1907, part iv., was brought into operation, and from that time until the end of the year 620 samples of milk were taken, principally from churns at the large railway stations. Of the samples in which it was found practicable to make a complete examination, 11.6 per cent. were found to be tuberculous. The farms supplying the

¹ Report of the Public Health Committee of the London County Council, submitting the Report of the Medical Officer of Health of the County for the Year 1908. (London: P. S. King and Son.) Price 3s. 6d.

samples giving positive results were inspected by the council's veterinary inspector; 4997 cows in all were examined, and of these 147 were found to present tuberculous udders. Provincial local authorities have shown willingness to cooperate with the council in preventing the sale of milk from cows which the council's veterinary inspector has certified to be suffering from tubercular disease of the udder, and in a few instances veterinary inspectors have been appointed by the local authorities to deal with this danger.

The report by Dr. Kerr upon the medical work of the council, as the education authority, deals with a period for the twenty-one months ending December 31, 1908. This period has been marked by great activity in all matters concerning school hygiene and the physical care of children. There are, in the opinion of the medical officer, further and wide-reaching changes in prospect. He states:—"Any public provision for protecting and aiding growth and development of children during the years of school life—three to sixteen years of age—should be entirely committed to the Education Authority. This would allow such matters as feeding, teaching, cleansing, medical treatment, or social protection of school children, when these duties become a public care, to be administered by the one authority, and by bringing all the various problems into a correct relation and perspective would also effect considerable financial economy. On the other hand, transient conditions in which the child bears the same social relations as any other individual, as for instance when affected with typhoid or scarlet fever, or when guilty of a crime, would still come under the same provision by the Sanitary Authority or Police respectively as at present. Fortunately this is the line taken by all the recent legislation in matters concerning children."

The educational work of the county council which falls under the direction of a medical officer is very extensive, embracing the examination of candidates for employment and scholarships; medical inspection of school children, including the inspection and the hygienic condition of school premises, &c.; a large amount of work to promote cleanliness and to prevent communicable disease; and prescribing the special school work amongst the scholars in schools for the mental or physically defective, the blind or deaf, &c. The medical staff at the end of 1908 numbered fifty-two, and it has been decided to increase the staff by the addition of sixteen school doctors in the summer. The school nursing staff consists of a superintendent, two assistants, and fifty-one school nurses; these undertake the oversight of personal hygiene in both elementary and secondary schools. Upon the subject of underfed school children, the medical officer directs attention to the fact that there is no certain criterion of this condition, and it seems often quite impossible to distinguish between bad feeding, improper feeding, and bad home conditions. The treatment of those children in whom medical inspection discovers defects has received a great deal of consideration at the hand of the county council. A solution has not yet been arrived at, but it is certain that visual troubles, discharging ears, ringworm, and conservative dentistry are matters on which neither the private practitioner nor the hospitals can give sufficient or satisfactory relief, and the establishment in London of school clinics to deal with these conditions amongst school children will probably be the eventual solution. The work of the school nurses was almost entirely directed to effecting the cleansing of scholars' heads, bodies, and clothing. Nearly twenty thousand children are known to the nurses as uncleanly in these respects. That such conditions are tolerated gives an idea of the conditions of the homes, which are often so dirty and dark, and wanting in the means of cleansing, that it would be an injustice to exclude such children and prosecute the parents. It appears that the municipal cleansing stations provided for cleansing verminous persons are inadequate to deal with all these cases. The Children's Act, 1908, gives power to the education authority to examine and cleanse these children in default of the parents, and it looks as if that authority will have to make some provision for dealing with these cases, at least in some parts of the metropolis.

The open-air schools provided by the council (four in number) are doubtless doing a great service, physically and

educationally, to children with ailments which unfit them to take their place in the school class-room with the ordinary scholars. Children with scrofulous and tuberculous conditions, anæmia, adenoids and enlarged tonsils, heart disease, and certain bone, nervous, and eye diseases, profit considerably by a few months in these open-air schools.

PROBLEMS OF THE SOUTH-WESTERN HIGHLANDS.¹

THE southern Highlands of Scotland consist of a complex series of gneisses, schists, crystalline limestones, and quartzites, trending across Scotland approximately from south-west to north-east. These metamorphic rocks are bounded abruptly to the south by the Highland boundary fault, which brings them against Upper Palæozoic rocks. Their northern boundary is less regular, and is generally the junction with the Moine gneiss, the rock which occupies so much of the Northern and Central Highlands. The schists and the associated rocks between the Moine gneiss and the boundary fault may be conveniently grouped together, under the name proposed by Sir Archibald Geikie, as the Dalradian system.

The most important difficulty in the interpretation of these rocks is the uncertainty as to which is the upper and which the lower end of the succession. According to Nicol, the southern members are the youngest, and there is a descending series to the north. This view is contradicted by many obvious facts in the field geology, and the view is therefore widely held that Nicol's order must be reversed, and that the beds of the southern margin are the oldest. One serious difficulty in the second view is that the southern rocks are much less altered than the northern, and this theory therefore involves some measure of selective metamorphism. Several ingenious interpretations have been advanced to overcome this difficulty. The author of the address, however, held that both views as to the order of succession are correct in parts. For convenience of reference, the Dalradian system may be divided into five series, which, with their relations to the other pre-Cambrian rocks, are shown in descending order, as follows:—

Algonkian	Torridon Sandstone		
	Main sequence		On Southern Margin
	(5) Schichallion Quartzite	(4) Blair Atholl Limestones and Black Schists and interbedded Quartzites	Age ? Upper Dalradian or later
	(4) Ben Lawers series		Aberfoil Slates and Grits
Dalradian	(3) Loch Tay Limestones and associated garnetiferous mica schists	(2) Loch Lomond Gneiss	Ben Ledi Schistose Grits
Caledonian	Moine Gneiss and associated schists		
Lewisian	Lewisian Gneiss		

This classification adopts Nicol's succession in part, as it accepts the Aberfoil and Ben Ledi series as younger than the Loch Lomond gneiss, against which they rest, and it is consistent with the less altered condition of the southern rocks and the steady diminution in the metamorphism of the rest of the rocks going northward, as, for example, from the Loch Lomond Gneiss to the Loch Awe Grits, and from the garnetiferous mica schists of the Loch Tay series to the black schists and unfoliated quartzites near Blair Atholl.

The evidence in some points of this succession is still incomplete, especially as regards some of the rocks within easy access of Glasgow. The special points on which

¹ Abstract of the Presidential Address delivered to the Glasgow Geological Society, by Prof. J. W. Gregory, F.R.S.

further research would be most useful were therefore mentioned in the hope that the members of the Glasgow Geological Society would investigate them.

The problem is of interest from its bearing upon the early geological history and geography of north-western Europe. The structure of western Europe has been dominated by the formation of three great mountain systems, each due to pressure usually from the south, and each having its younger rocks exposed mainly on the northern flanks of the chain. The youngest is the Alpine system, formed mainly in Upper Cainozoic times, and including the Pyrenees, Alps, Carpathians, &c. A somewhat similar mountain system, of which fragments remain in southern Ireland, Devonshire, Brittany, and Germany, had been formed in Upper Palaeozoic times; from its analogy with the Altai Mountains of Asia, Suess has called its mountains the European Altaids. Still earlier, in later Archæan times, there was formed the first of these European mountain systems, of which fragments occur in northern Ireland, the Grampians, and Scandinavia. There are many interesting analogies between these old Grampians and the later Altaids and Alps. The old mountain system to which the Grampians belonged probably extended far westward into the North Atlantic, and to its influence may be attributed the desert climate of Scotland during the deposition of the Torridon Sandstone.

THE ETIOLOGY OF LEPROSY.

THE eighteenth report of the Board of Health on leprosy in New South Wales contains the usual careful clinical records of the features of the disease in the patients admitted during the year, as well as a record of all the cases occurring in the Commonwealth during 1908. No case of leprosy has ever been heard of in Tasmania. In the other States the disease occurs apparently most frequently in Chinese and in aboriginals, and is more frequent in northern than in southern territories.

An account is given of a systematic test of Prof. Deycke's "nastin" treatment. Nastin is a vaccine made from a leptothrix found in some recent Lepromata, and not from the bacillus lepræ. It is pronounced valueless, any beneficial result being assigned to the natural fluctuations in the progress of the disease; one or more cases of spontaneous cure are noted. For the rest, the report is remarkable for the scepticism the author, Dr. J. Ashburton Thompson, expresses on the etiology of leprosy and on the value of isolation as a preventive of transference of the disease.

It will be remembered that the International Congress at Bergen last year endorsed the view that the bacillus lepræ of Hansen was the etiological agent. Dr. Thompson's views are seemingly published as a protest, and, holding the views he does, it is gratifying to learn that Dr. Thompson recognises that, as the presiding and executive member of the central health authority to which the Leprosy Act is entrusted, he has a clearly defined duty to perform, and that he performs it, notwithstanding his thinking "the *mère idée* on which that law is based to be of doubtful utility," and his statement, "I can at all events safely assert that its validity has not been demonstrated." One would have thought that the success which has attended the practice of isolation in Norway during the past forty years afforded sufficient evidence of its value even to the most sceptical, for Hansen's prophecy some forty years ago that in 1920 there would be no leprosy in Norway is in more than a fair way of being fulfilled.

HELIUM IN AIR AND MINERALS.

AN interesting paper on the occurrence of helium in the air of Naples and in minerals from Vesuvius is published by Prof. A. Piutti in the *Rendiconto* of the Royal Society of Naples (third series, vol. xv., p. 203). It is well known that in 1881 Prof. Palmieri read a paper before the same academy in which he claimed to have recognised the characteristic line D₃ of helium in the flame spectrum obtained by heating in a Bunsen flame "an amorphous, buttery substance of a yellow colour which was found as a sublimate on the edge of a fumarole

near the mouth of Vesuvius." This is generally accepted as the first discovery of terrestrial helium, although Nasini and Anderlini in 1906, on examining the flame spectrum of a large number of volcanic incrustations, failed to recognise the presence of helium in any of the specimens they examined under the conditions described by Palmieri.

Prof. Piutti has now investigated with especial care, and by an ingenious method, the gas evolved on heating several Vesuvian minerals. The gas was expelled by heating the mineral in a quartz tube connected, through a three-way cock, with a Plücker tube, a Gaede air-pump, and a glass bulb containing cherry-stone carbon, which could be cooled to -192° C. The latter served to absorb nitrogen and inert gases other than helium. All air was first entirely removed from the apparatus by the Gaede pump, special care being taken to ensure its complete absence prior to heating the mineral and during the course of the experiments. When the carbon is cooled by liquid air and the vacuum applied, any nitrogen present is first absorbed by the carbon, and the lines of argon and neon appear until the kathode space is formed. At this point, if even the smallest trace of helium is present, the D₃ line is seen distinctly by the side of the sodium lines. Control experiments showed that 0.073 cubic mm. could be detected in the apparatus employed. Helium can also be detected in the same way in 3.5 c.c. of ordinary air.

The examination of several radio-active forms of sanidine from Vesuvius showed that the radio-activity was due to particles of zircon contained therein. This zircon was found to evolve helium, and other samples of zircon from different localities, Italian and otherwise, were also found to contain helium in varying proportions. No relation could, however, be traced between the proportion of helium and the radio-activity or density of the samples. The Vesuvian zircon had the highest radio-activity, but the proportion of helium was relatively low.

THE SUGAR INDUSTRY IN HAWAII.¹

HAWAII and its associated islands, Maui, Oahu, Kauai and others, form a volcanic group in the Pacific 20° north of the equator, largely devoted to sugar production. In 1895 the Sugar-planters' Association established an experiment station at Honolulu, and some five years later the islands were annexed by the United States. The enormous importance of these two events is reflected in the statistics for sugar production:—

	Hawaii	Maui	Oahu	Kauai	Total
1895	61,643	27,735	17,433	42,816	149,627 tons
1896	109,259	29,097	35,782	51,650	225,828 "
1900	115,224	57,347	53,625	63,348	289,544 "
1901	134,618	58,349	99,534	67,517	360,038 "
1905	126,405	100,414	123,095	76,314	426,248 "
1908	180,159	122,629	137,013	81,322	521,123 "

The increase during the fourteen years has been from less than 150,000 tons to more than 520,000 tons, and detailed statistics show that the produce per acre, as well as the total acreage, has increased.

Practically all phases of the sugar industry are dealt with at the experiment station. Varieties of canes are tested, seedlings are raised and examined, and the effect of change of variety is investigated, the object being always to obtain plants more prolific, better adapted to the local surroundings, and more resistant to the local diseases or insect pests than those at present grown. Considerable attention is paid to insect pests, which naturally do an increasing amount of damage as cultivation becomes more and more intense. Methods of working up the sugar are also studied, the chemical and milling problems involved are gone into, nothing within the power of the staff and likely to benefit the planters being omitted.

In consequence there is a constant tendency to economy in production; thus in the early years fertilisers were often applied without any reference to the specific requirements of the crop or the general deficiencies of the soil; now, however, these, and also climatic considerations, are taken into account, and the staff are able to give useful definite information as to the mixture of fertilisers required.

¹ Tropical Life, No. 2, vol. vi., 1910. Bulletins of the Sugar-planters Associations, Hawaii.

Relatively large quantities of nitrogenous and of potassic manures are found necessary, phosphates being less needed; to meet this demand, potash salts and nitrate of soda are now imported in quantity. Ten years ago there was practically no importation of these manures.

A certain amount of the land has to be irrigated, especially that occurring on the leeward side of the high land forming the interior of the island. On the windward side, however, the rainfall is higher and irrigation is not necessary. On the island of Hawaii itself most of the plantations are unirrigated, but on the other islands irrigation is very general. Here, also, useful help has been given by expert engineers in ascertaining the cheapest effective way of obtaining the necessary water.

NATURAL SCIENCE IN BENGAL.

THE annual report of the Asiatic Society of Bengal for the year 1909 has now been published. We notice that the society celebrated its 125th anniversary on January 15, 1909. The celebration took the form of an evening reception held in the Indian Museum. Many scientific, archæological, philological, and historical exhibits were shown, illustrating the progress and activities of the society. The council awarded the Barclay memorial medal for 1909 to Lieut.-Colonel David Prain, F.R.S., I.M.S. (retired), in recognition of his biological researches.

The total number of contributions to the society under the heading mathematics and the natural sciences was seventeen. Commenting on these, the report points out that Mr. Hooper's paper on *Tamarisk manna* shows that the chief sugar in it is not mannite, but a saccharose. Babu Bidhu Bhusan Dutta, in a contribution on the constituents of the roots of *Arisaema concinnum*, Schott, and *A. speciosum*, Mart., shows that these two famine foods contain much nutriment, chiefly starch. Mr. B. L. Chaudhuri directed the attention of the society to the mosquito-larvæ eating propensity of fish of the genus *Aplocheilichthys*, and asked for cooperation in making further observations. Several species of this genus of small fishes are voracious feeders on the larvæ.

Babu Nibaran Chandra Bhattacharjee directed attention to the way in which *Marsilia quadrifolia* fruits only when the water in which it has been growing recedes from it and leaves it dry. Mr. H. Martin Leake's paper on Indian cottons is of importance. His object is to breed early cotton suitable for cultivation at Cawnpur, with the good tint of the slow-maturing cottons; he has observed the characters in bud development which lead to early or late maturity in order to recognise such as combine with the desirable quantities in the lint. Mr. E. P. Stebbing, in a paper on the *Loranthus* parasite of the Moru and Ban oaks (*Quercus dilatata*, Lindl., and *Quercus incana*, Roxb.), shows how destructive the parasite is to these oaks in the neighbourhood of Naini Tal and in Kumaon. Sir George King's "Materials for a Flora of the Malayan Peninsula" has been continued. Accounts of the orders Gesneraceæ, by Mr. H. N. Ridley, and Verbenaceæ, by Mr. J. Sykes Gamble, have been received. Mr. Burkill has diagnosed two varieties of the lemon oil grass, *Cymbopogon Martini*. Prof. P. Brühl has contributed a paper on recent plant immigrants into Bengal; 234 species are named by him; their origin is discussed and the causes of their introduction. America supplied 54.7 per cent. of these immigrants.

THE DEVELOPMENT OF ELECTRICAL POWER AT NIAGARA FALLS.¹

THE development of electrical power at Niagara Falls has long attracted widespread attention and interest. Since the first installation upon the American side, descriptions and discussions of its works and methods have been granted a conspicuous place in technical records and the scientific Press, but the fact is apparently less known that there now exist at Niagara four more installations, each larger than the pioneer plant, and one at least differing from it to a very marked degree in the method in which

the turbines are employed and coupled to the electrical generators.

The author, having paid a visit to Niagara in December, 1907, when exceptional opportunities were afforded him of inspecting the whole plant of the Ontario Power Company, takes the present opportunity of recording the following notes, which may supplement the knowledge of the subject hitherto available, especially so as, after the completion of these notes, correspondence took place with the Ontario Power Company with the object of eliciting further information, and photographs were received illustrating the operations of the company.

Scheme.—Briefly outlined, this company's development comprises the taking of water from the Upper Niagara River above the Horseshoe Fall, leading it through pipes and penstocks to turbines in a station below the Fall, and there utilising its energy for the generation of electricity, which is transmitted to a second station on the hill above, and thence distributed. There is a fall in level of 55 feet in the rapids above the Horseshoe Fall, and to take advantage of this the headgates are placed just above the rapids. From the headgates three great steel and concrete tunnels or conduits, laid below the surface of the Victoria Park, will convey nearly 12,000 cubic feet of water per second to the top of the cliff above the power-house, and just beyond the Fall. Thence it will pass through twenty-two steel penstocks in shafts and tunnels down and out through the cliff to an equal number of horizontal shaft turbines in the power-house below, which is situate on the water edge immediately at the foot of the Horseshoe Fall. From the generators, the electrical cables will pass through tunnels to the twenty-two banks of switches, transformers, and instruments in the distribution station on the hill above, and thence to the transmission lines beyond, the whole installation, when complete, being capable of an output of more than 200,000 horse-power.

The intake works for the entire 200,000 horse-power are now finished. One of the three main conduits is completed and in use, while the portals and headworks for the second and third tunnels are completed, and a portion of the excavations made. Six of the twenty-two penstocks are completed, and with their turbine-sets are at work, and at the time of the author's visit the seventh was practically completed. The distribution-station building is complete for the switchboard of the entire twenty-two units, for the transformers of eight, and the other apparatus of fourteen units, and is well ahead of the developments in the power-house.

The most important engineering features wherein this latest company differs from its predecessors are the arrangement of intake works, the design of main conduit and spillway, the horizontal shaft turbine units, the symmetry of arrangement of the whole, the centralisation of control, and the protective isolation of the various apparatus.

Particulars of Niagara River and the Falls.—The total drop in the Niagara River in its course of thirty-six miles between Lake Erie and Lake Ontario is 326 feet, of which 216 feet is in the Falls and the rapids immediately above them.

The American Fall is 167 feet high and 1000 feet in width, while the Horseshoe Fall is 150 feet high and 2600 feet in width. The greatest depth of the river immediately below the Falls is about 102 feet. It is estimated that an average of 222,400 cubic feet of water pass over the Falls each second. This is 25,000,000 tons per hour, or about one cubic mile a week, and represents a kinetic energy of nearly 5,000,000 horse-power. At the headworks of the Power Co. the river is 3400 feet wide, and flowing at an average velocity of about 8 feet per second.

Intake.—These works have been placed and designed, not only to take advantage of the additional height of the rapids as mentioned above, but also with special reference to the ice difficulties, which have been the limiting factor in the success of Niagara power. Cake-ice in enormous quantities floats down for weeks at a time from the Great Lakes, and mush-ice is also formed in the rapids, primarily by the freezing of spray and foam, and secondarily by the disintegration of cake-ice. The latter trouble is avoided, since the intake is in the smooth water just above the

¹ From a paper entitled "An Account of a Visit to the Power Plant of the Ontario Power Co. at Niagara Falls," read before the Institution of Mechanical Engineers on January 7, by Mr. C. W. Jordan.

rapids at a place where the current is very swift. To exclude the former trouble, the following precautions have been taken:—a long and tapering forebay, protected at the entrance by the main intake, terminates at its narrow down-stream end in a deep spillway. Upon the river side it is enclosed by a submerged wall, while the other side, near the spillway, is occupied by the main screen building leading to the inner bay and to the portals and headgates of the three conduits.

The intake, which is nearly 600 feet long, stretches across the inlet at Dufferin Island almost parallel with the current in the river. Throughout its whole length, a concrete curtain wall extends down 9 feet into the water, which is 15 feet deep at this spot, so that the gate openings beneath admit only deep water, and this at right angles to the swift exterior surface flow, which, sweeping the full length of the curtain wall, carries the floating ice past to the rapids beyond.

The intake is divided into twenty-five bays, through

to the inner bay, and parallel with the direction of flow in the outer bay. Here again a curtain wall formed by the front wall of the superstructure admits only deep water to the screens at right angles to the main current, while it also excludes ice with the surface currents maintained through the forebay by a huge spill of surplus water. At the gate structure, where the water is 30 feet deep, the tapering portals leading to the electrically operated Stoney headgates are protected with wide-meshed screens which are also enclosed and safeguarded by a curtain carried by the front wall of the gate-house. There is an ample ice-run from the bay in front of the curtain to the river, and both at the headgates and screens an open canal spills into a gravity ice-run emptying into the river. Both buildings are supplied with steam for heating and thawing from an underground boiler plant, and the author can testify to the entire success of the heating. It was a bitterly cold day, snowing and freezing hard, with a nasty wind, but inside these houses it was almost unpleasantly hot, in

FIG. 1.—Power District of Niagara Falls.

which the water is admitted at a velocity of 5 feet per second. Provision is made for inserting stop-logs into each of the twenty-five openings in order to regulate the flow of water.

The outer forebay has an area of 8 acres, and a depth ranging from 15 to 20 feet, and is bounded on its down-stream side by a submerged wall or dam 725 feet long, terminating at the down-stream end of the screen-house, which is 320 feet long, built of reinforced concrete faced with Roman stone.

The inner forebay is 2 acres in area with a depth of 20 to 30 feet, whilst the gate-house, similar in construction to the screen-house, is 120 feet long and divided into six bays, two for each of the main conduits. The 18-foot "Stoney" gates which guard the entrances to the conduits weigh 18 tons each, or 36 tons including the counter-balance. They were built by Ransomes and Rapier, and are operated by electric motors of 5 horse-power capacity.

At the main screen the same precautions for the exclusion of ice are repeated. This structure, which is 320 feet in length, in 20 feet depth of water, lies across the entrance

spite of the large masses of ice-cold water coming in continuously from the river. The water before entering the conduits must pass through three automatically selective steps, each excluding ice, and, in addition, through two screens, each behind ice-runs, in heated buildings containing live steam for emergencies, and the experience of three winters has proved the above plan of excluding and preventing the formation of ice to be an entire success—a record which is unprecedented for power plants in a climate like that of Niagara.

An electric overhead travelling-crane runs along the screen-house for removing the screen-frames for cleaning and changing when necessary, and as this building is situate in the park the roof is flat and finished off as a promenade, access being obtained from the outside by broad steps at either end of the building, and from this point a magnificent view of the upper rapids is obtained.

Main Conduits.—These are of 0.5-inch rivetted and reinforced steel embedded in concrete 18 feet and 20 feet in diameter and 6500 feet long, sunk beneath the surface of the park. The water flows through them at an approxi-

mate velocity of 15 feet per second. The only conduit at present in service has a sectional area of 254 square feet, and is capable of supplying sufficient water for the operation of six generators at full load. The second and third conduits have not as yet been installed. Just beneath the top of the cliff, behind the power-house, is a long underground chamber 274 feet long, 10 feet high, and 16 feet wide, with an arched concrete roof to support the conduit above. Rivetted to the bottom of the main conduit are seven large tapered steel castings leading to the 9-foot valves and penstocks below, each supplying water at 10 feet per second to a single horizontal shaft turbine in the power-house below.

Spillway and Weir.—The spillway at the end of the conduit, which is intended to prevent water-hammer in the case of sudden loss of load, is little more than the enlarged end of the main conduit, raised and fitted with an enclosed weir and underground discharge. The weir is adjustable as to height, and the discharge tunnel, after a steep initial pitch in the taper from the weir, follows a uniform grade and symmetrical curve while circling about to reach the river in a helix, thus preserving a water column which is smooth and unbroken, of highest velocity and least expenditure of energy. This has the effect of preventing erosion, restricted flow, and excessive air-suction, the latter on account of the danger of ice forming from the spray under forced circulation of air.

Location of Power-house.—The power-house is situated on the river bank nearly at water-level and close under the Horseshoe Fall, and it is an interesting and important point that the full head of water between the upper and lower rivers has been acquired so far as was possible from an economic standpoint, while the huge and costly excavations rendered necessary in the previous schemes have also been dispensed with, resulting in a greatly reduced capital expenditure.

Owing to limited space, the generating station is only 76 feet wide, but when completed it will be nearly 1000 feet long; the generating units stand side by side in a single row right down the centre of the building, the turbines being on the land side and nearest their source of supply. The space between them and the rear wall is occupied by a gallery, upon which are mounted the oil-pressure governors, each almost over the end bearing of the turbine it controls.

The mean water-level at the generating station is 343 feet above tide, though it varies from 338 to 365 feet. The walls of the generating station are of concrete, the rear wall being 12 feet thick at the bottom and the river wall 9 feet.

Generating Units.—Each generating unit consists of a horizontal double turbine direct coupled to a generator. The completion of the station and its equipment will be but an extension of the present form until, according to present plans, there will be an installation under the one roof, capable of continuously delivering 200,000 horse-power of electrical energy. Three of the generators, which are all of the conventional horizontal shaft pattern and exactly alike in appearance, have a capacity of 10,000 horse-power each, while the others have each a capacity of 12,000 horse-power. These machines are wound for three-phase current at 12,000 volts and 25 cycles, and have revolving fields, the revolutions being 187.5 per minute. The total weight of each generator is 231 tons, and each was entirely assembled on the spot, including the building up of the laminated iron rotor and the winding and insulating of the armature.

Turbines.—The turbines were made by J. M. Voith, Heidenheim, a. d. Brenz, Germany, and are of the Francis or inward-flow type, double, central discharge or balanced twin turbines, and are designed to deliver 12,000 horse-power at 175 feet head. Their shafts are 24 inches maximum diameter, and each carries two 78-inch cast-steel runners of "normal" reaction. The housings are of reinforced steel plates 16 feet in diameter, spiral in elevation, and rectangular in plan. Gates are of the wicket or paddle type, and the rotating guides forming them are carried by shafts which project through stuffing-boxes to an external controlling mechanism worked by the governors, thus freeing the casings from the objectionable internal-gate rigging, and leaving the approaches to the

guides uniform and open. Whilst the velocities in housings and draft-tubes are high, corresponding losses are avoided by easy changes of velocity and direction, and large curves free from acute angles or obstructing projections.

Leads.—The leads from the generators are single conductors, insulated with treated cambric. These leads, each in a separate compartment, are mounted on porcelain insulators, ample clearance to earth being allowed everywhere; the compartments are built up of thin shelves of reinforced concrete fastened to the concrete substructure of the power-house, and are closed by asbestos doors readily removable for inspection. At no place are the leads of more than three generators brought near one another, and the leads of each set of three generators, where they approach their respective oil-switches on the gallery, are so protected and isolated from each other that earths or short circuits are impossible. Field circuits, exciter leads, and control wires are carried in iron conduits, and are either in separate passages or at a proper distance from the main wires.

Distributing Stations.—The generating and distributing stations are parallel, and nearly 600 feet apart, with a difference of 260 feet in elevation. The distributing station is wider and shorter than the power station, and is divided into three longitudinal bays or five main sections. The narrow front bay contains the switches, bus-bars, &c., at generator pressure; the wider rear bay contains those at transmission pressure. Between these bays is the main middle bay, divided transversely by a three-floor switch-board section into two long transformer-rooms. The projecting central bay is utilised as offices. The transformers stand along the centre of the two rooms in groups of three, corresponding in position and capacity to their respective generators. Similar apparatus is arranged in rows parallel with each other and with the generating units. Unit values corresponding to the generators in capacity and position are maintained throughout. Thus each generating unit has its individual cables, switches, and switchboard, section of bus-bars, transformers, interrupters, and high-pressure switches complete to the transmission lines, enabling independent operation as an independent power plant, or, through the selector switches, and duplicate sectional bus-bars, the operation of all units in any combination of groups, as readily and perfectly as their operation in parallel.

Transformers.—The low-pressure bay contains on the main floor the 12,000-volt automatic oil circuit breakers in double column, and in the chamber beneath only the sectional duplicate bus-bars and their immediate connections. In the transformer-rooms the transformers stand in pits 6 feet below floor-level, and parallel with them, adjacent to the high-pressure bay, are corresponding pits for choke-coils or other protective apparatus. Beneath, and between the foundations, are laid the various systems of piping for water, oil, and drainage, and the main cableways to the transformer above. Each transformer is fitted with a recording thermometer, and is of the oil-insulated, water-cooled type, three to a unit, connected in delta on the low voltage, and in star with centre grounded on the high-voltage side. The secondary potential of each transformer is 36,000 volts, and, as connected, the resultant line voltage is approximately 62,000 volts. Each transformer has a normal capacity of 3000 k.v.a., and weighs, complete with oil and case, approximately 50 tons. They are cylindrical in form, and the three constituting a unit are arranged in a triangular group in the pit.

Recording Instruments.—The graphic recording instruments are of a new type, and comprise voltmeters, ammeters, wattmeters, and frequency and power-factor indicators. They are so connected in the low-voltage circuits that there is a continuous record of each generator as well as of the demands of any set of feeders. In the control-room, the chief operator's position is in the centre, where at his desk he may observe, by means of his instruments, every electrical occurrence, and direct his assistants as required. He has his own private telephone system running to all the rooms in the building, and also has direct connection with telephones along the transmission wires. The telautograph is invariably used for communicating with the generating station, because of its un-

mistakable records. The chief operator is thus able, without moving from his chair, to control every electrical circuit and situation of the system, and to stop, start, regulate, or synchronise each unit. He can throw the output of each unit through its transformer to the transmission as if from a single isolated plant, or he can throw the current upon either bus-bar while supplying its transformers from the same or another bus-bar. The experience obtained up to the present in the practical working of the plant has been so successful that it is to be anticipated that other large plants in the future will adopt the same system.

Distribution of Power by the Ontario Power Co.

Two 60,000-volt lines run from the distributing station for six miles to a point on the Niagara River near the town of Queenstown, where they cross the gorge, and connect with the lines of the Niagara, Lockport, and Ontario Power Company delivering power for use in the United States. These lines consist of aluminium conductors $1\frac{1}{2}$ inches in diameter, carried on steel towers 55 feet high to the top wire, with an average span of 500 feet. The insulators for this line are of porcelain, and weigh 35 lb. each.

The first of the transmission lines was put into operation on July 7, 1906, and the plans realised at present, and contemplated for the immediate future, in the plant of the Niagara, Lockport, and Ontario Power Co., involve a maximum transmission distance of 160 miles. This distance puts the plant amongst the longest transmissions of the world.

Size of Cables.—There are only three sizes of cables used on the main transmission lines, designated by the company as $3/3$, $2/3$, and $1/3$ respectively. The $3/3$ cable is aluminium cable, consisting of nineteen strands, and having a total area of 642,800 cir mils, being equivalent to 400,000 cir mils copper. The areas of cross-section of the other cables are respectively two-thirds and one-third that of the large one.

It is impossible to enumerate the manifold purposes for which the power is used, but some of the more important are the following:—

Light.—The power generated at this station and sent out over the above-described transmission lines furnishes part or all of the public and private lighting in Niagara Falls, Welland, Stamford, and St. Catharines, Ontario; and Lockport, Depew, West Seneca, Hamburg, Batavia, Rochester, Canandaigua, Auburn, Baldwinsville, Phoenix, Fulton, and Syracuse, New York.

Heat.—The same power operates electric furnaces for the reduction of iron, copper, and other ores, and the manufacture of cement, calcium carbide, and lime nitrates in Port Colborne, Welland, Niagara Falls, and Thorold, Ontario, and Lewiston, Lockport, and Caledonia, New York.

Power.—The same power operates wholly or in part the trolley systems in Syracuse, Rochester, Canandaigua, Geneva, West Seneca, and Hamburg; and the interurban lines Syracuse, Lake Shore and Northern Syracuse and South Bay, Rochester and Geneva, Rochester and Mount Morris (Erie Railroad), Buffalo, Lockport and Rochester, Buffalo and Hamburg, and Buffalo and Dunkirk (partly constructed). It operates the steel works of the Ontario Iron and Steel Company at Welland, Lackawanna Steel Company (7000 employees), Shenandoah Steel Wire Company, plate-rolling mills of Seneca Iron and Steel Company, and pumping works of Depew and Lake Erie Water Company at West Seneca; repair shops of the New York Central and Hudson River Railway Company, and Delaware, Lackawanna and Western Railroad Company, and the works of the Gold Coupler Company at Depew, stone-crushing establishment of the Kelley Island Lime and Transport Company at Akron; works of the United States Gypsum Company at Oakfield, and various smaller industries located on main transmission lines.

The utilisation of a portion of the vast energy of Niagara without in any way detracting from the splendour or beauty of the Falls is destined to create in the Ontario peninsula and in western New York a vast manufacturing district.

SCIENTIFIC WORK OF THE SMITHSONIAN INSTITUTION.

THE report of Dr. Charles D. Walcott, secretary of the Smithsonian Institution, for the year ending June 30, 1909, has just been issued. All the numerous departments of the institution's activity receive attention, but it is possible here to deal only with the more direct scientific work accomplished during the year under review. Subjoined is a summary of the parts of the report dealing with matters of scientific interest.

Smithsonian African Expedition.

Through the generosity of friends of the institution, there was provided during the year a special fund to pay for the outfitting and to meet the expenses of the naturalists on a hunting and collecting expedition to Africa under the direction of Colonel Theodore Roosevelt. No part of the fund was derived from any Government appropriation or from the income of the institution. The special interest of the institution in the expedition is the collection of biological material for the United States National Museum.

The party sailed on March 23, 1909, from New York, whence steamer was taken to Mombasa, British East Africa. The expedition arrived in Africa on April 21. A letter, dated at Nairobi, May 31, announced the shipment of twenty barrels of large mammal skins in brine, comprising Colonel Roosevelt's first month's collection. While no new species, so far as is known, is included in this first shipment, the collection will supplement materially the specimens already in the National Museum. Together with this shipment are expected a large number of specimens of small mammals, and also of birds. Through the Smithsonian African expedition the National Zoological Park has been presented with an exceptional collection of live African animals.

Cambrian Geology and Palaeontology.

Dr. Walcott's studies of the older sedimentary rocks of the North American continent, which he has been carrying on as opportunity offered for more than twenty years, were continued in Montana and the Canadian Rockies during the field season of 1908. The scientific results of the 950-mile trip through the forests and on mountain trails will aid materially in the solution of several problems connected with the stratigraphy and structure of the main ranges of the eastern Rocky Mountains and of the geological position and age of many thousands of feet of the sandstones, shales, and limestones forming the mountains in northern Montana, British Columbia, and Alberta. On the return an examination was made of the geological formations in the vicinity of Helena, Mont., and of the Wasatch Range, south-east of Salt Lake City, Utah. Three additional papers giving a summary of the results of these studies in Cambrian geology and palaeontology were published during the year.

Researches on Atmospheric Air.

A Hodgkins grant was approved in October, 1908, for the erection of a small stone shelter on the summit of Mount Whitney, California, for the use of investigators during the prosecution of researches on atmospheric air, or on subjects closely related thereto. The pioneer trip to the summit of Mount Whitney in the summer of 1881 by the late secretary, Dr. Langley, at that time director of the Allegheny Observatory, will be recalled in this connection, as well as his conviction that in no country is there a finer site for meteorological and atmospheric observations than Mount Whitney and its neighbouring peaks.

Mr. C. G. Abbot, who succeeded Secretary Langley as director of the astrophysical observatory of the Smithsonian Institution, and to whose immediate suggestion and earnest personal efforts the preparation for and the establishment of this important post on Mount Whitney are largely due, began his observations there in the summer of 1909, and obtained important data in the determination of the solar constant. The cooperation of Prof. W. W. Campbell, the

director of Lick Observatory, University of California, at Mount Hamilton, has been most helpful during the erection of the shelter. The class of researches to be prosecuted at this exceptionally favourable station are not only of great scientific interest, but are expected also to prove of value in determining questions having a direct, practical influence on the preservation and progress of human life on our globe.

International Standard Pyrheliometers.

A limited grant from the Hodgkins fund was approved in February, 1909, for the construction of several silver disc pyrheliometers. These instruments are to be placed in charge of scientific investigators in widely separated localities for the purpose of establishing an international scale for the comparison of observations on solar radiation. The varying results published by observers have made the need of international cooperation in this connection apparent, and the matter has received considerable attention at conferences of the Solar Union. These simple and comparatively inexpensive instruments are to be constructed after a design by Mr. Abbot. Similar pyrheliometers have been employed in the researches of the Astrophysical Observatory for several years, and have proved entirely satisfactory.

Langley Medal and Memorial Tablet.

As a tribute to the memory of the late secretary, Dr. S. P. Langley, and his contributions to the science of aerodromics, the regents of the institution adopted the following resolution on December 15, 1908:—"That the board of regents of the Smithsonian Institution establish a medal to be known as the Langley medal, to be awarded for specially meritorious investigations in connection with the science of aerodromics and its application to aviation." Following the establishment of this medal, a committee of award, composed of gentlemen of recognised attainments in the science of aerodromics, was appointed. The committee recommended that the first medal be bestowed on Messrs. Wilbur and Orville Wright, and the medal was awarded on February 10, 1909. Designs for the Langley memorial tablet are now being prepared by a well-known architect of Washington.

National Museum.

More than 250,000 specimens were added to the museum collections during the year, about 200,000 of them pertaining to biology and the remainder to geology and anthropology. One of the most important additions to the division of ethnology was a contribution from Dr. W. L. Abbott, consisting of about 500 objects from south-western Borneo. To the technological collections were added more than 200 objects transferred from the United States Patent Office. The department of biology received a noteworthy gift of about 1200 European mammals and sixty-one reptiles from Mr. Oldfield Thomas, of the British Museum, and Mr. Gerrit S. Miller, of the National Museum. This has so greatly increased the importance of the National Museum collection of the mammals of Europe that it now ranks as one of the largest and most valuable in the world. Mention must also be made of a contribution of about a thousand mammals and birds of Borneo, received from Dr. W. L. Abbott.

In connection with the work of excavation and repair of the Casa Grande ruins in Arizona, under the direction of the Smithsonian Institution, there were collected and placed in the National Museum about 650 stone axes and hammers, rubbing and grinding stones, earthenware bowls and vases, pieces of basketry and textile fabrics, shell ornaments, and wooden implements. From similar excavations in the Mesa Verde National Park, Colorado, there were received about 500 objects of like character. The department of geology received a large series of Cambrian fossils from the Rocky Mountains, collected during Dr. Walcott's field studies in that region. There were also added to the collections many objects pertaining to mineralogy and palæobotany. Eighty-two regular sets of geological specimens to the number of 7739 were distributed during the year for educational purposes, besides 1300 specimens of geology, marine invertebrates, and fishes arranged in special sets.

Two field parties in which the institution and museum are greatly interested left America during the year for important collecting regions, from both of which valuable results may be expected. The first will explore Java and some of the adjacent islands; the second expedition is that under the direction of Colonel Theodore Roosevelt into British East Africa and more inland districts.

Bureau of American Ethnology.

The bureau has collected data relating to sixty families or linguistic stocks and upward of 300 tribes. It does not expect to study all the tribes in detail, but rather to investigate a sufficient number as types which may stand for all. It has seemed wise at this stage of the researches to prepare a summary of our knowledge of the tribes, and this has taken the form of a "Handbook of the Indians," of which one large volume is published and the second nearly through the press.

The people of the United States have two great obligations which the bureau is trying to fulfil:—(1) that of acquiring a thorough knowledge of the Indian tribes in the interests of humanity; (2) that of preserving to the world an adequate record of the American race which is so rapidly disappearing.

Recently much interest has been manifested in the antiquities of the country, more especially in the great pueblo ruins and cliff dwellings of the arid region, and the fifty-ninth Congress enacted a law for the preservation of these antiquities. A first step in making this law effective is their exploration. A second is the excavation and repair of the more important ruins to ensure their preservation and to make them available to the public and for study. Dr. J. Walter Fewkes, of the bureau, has continued the work of excavation and repair of the ancient ruins in the Mesa Verde National Park. During the year the repair of Spruce Tree House was completed, and at the end of June excellent progress had been made in uncovering and repairing the crumbling walls of Cliff Palace, the greatest of the ancient ruins of its kind in the United States.

There is need also for ethnological work in the Hawaiian Islands and Samoa, for the following reasons. It is regarded as most important that the Government should have definite and detailed information regarding the native inhabitants of these islands, which are under its control and for whose welfare it is responsible. It is not less a duty of the nation to preserve some record of this peculiar race for the purposes of history and science, as neglect will become a source of deep regret. An experienced ethnologist should make investigations regarding the history, social institutions, religion, and general culture of the people, and a physical anthropologist should study their physical and mental characteristics.

National Zoological Park.

The National Zoological Park during the year added 576 new animals to its collections, which offsets a loss of 562 by exchange, death, and return of animals, and brings the number of individuals on hand, June 30, 1909, up to 1416. The entire support of the park was derived from an appropriation of 19,000*l.* for general purposes, including the purchase, transportation, care, and maintenance of animals; the care and improvement of grounds; the construction and repair of all buildings, enclosures, roads, walks, and bridges. Of this amount, the increased price of necessary provisions and labour brought the cost of maintenance alone to about 17,000*l.* It was therefore possible to do little toward permanent construction or improvement.

Astrophysical Observatory.

The work of the Astrophysical Observatory during the year consisted:—(1) Of bolometric observations carried on at Washington on the brightness of different parts of the sun's image; also some experimental work on the transparency of the air for long-wave rays, such as the earth radiates. A computation of the results of these experiments is now far enough advanced to show their satisfactory quality. Precise knowledge of the selective absorption of our atmosphere for earth rays is still lacking; and contradictory views are still being expressed about this

important subject; hence it is hoped that these experiments will be useful in the study of the dependence of the earth's temperature on radiation.

(2) Spectro-bolometric measurements of the solar constant of radiation have been continued at the Mount Wilson Observatory in California. As in former years, evidences of a fluctuation of solar radiation were found in the results of the measurements thus far obtained. A new and improved standard pyrheliometer was found to be more satisfactory than the one used in 1906, and great confidence is felt in the results obtained with it. Efforts have also been made to carry the bolometric measurements much farther in the ultra-violet through the use of a large quartz prism, a large ultra-violet glass prism, and two magnalium mirrors.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The special board for biology and geology has appointed Mr. Leonard Doncaster, of King's College, to be superintendent of the Museum of Zoology, and the Vice-Chancellor has approved of the appointment.

GLASGOW.—Principal Sir Donald MacAlister, K.C.B., has been appointed to represent the Senatus of the University at the centenary festival of the University of Berlin in October next.

A scheme for the formation of a clinical branch of the medical school of the University, to be situated at the Royal Infirmary, was approved by a Parliamentary Commission, after a two days' hearing, on April 1. The provisional orders for the purpose contemplate the establishment of four professorial chairs at this infirmary, in addition to those held at the Western Infirmary, namely, those of medicine, surgery, obstetrics, and pathology. The necessary funds, amounting to about 2000*l.* a year, are provided for from existing endowments and by grants from St. Mungo's College, the Muirhead trustees, and other benefactors. All the instruction thus provided will be open to women students of the University as well as to men.

THE late Colonel G. E. Church, who died on January 4, bequeathed 1000*l.* to the Royal Geographical Society towards a fund for the enlargement of its premises or towards a new building for its use. He left to Harvard University his collection relating to North and South America, consisting of books of travels, voyages, explorations, boundary-line questions, geography, ethnology, and history, as well as all writings by Latin and American authors, to be known as the "George Earl Church Collection." Should the authorities of the University not accept this gift within four months of his death, then the collection is to be offered to the Brown University, Rhode Island, or the Stanford University, in California.

In Class iv. (Education, Science, and Art) of the Civil Service Estimates for the year ending March 31, 1911, the estimate amounts to 18,651,483*l.*, a net increase of 697,718*l.* on the amount voted in 1909. The estimate for the Board of Education shows a net increase of 417,663*l.*, of which 348,775*l.* arises under the subhead of grants in respect of public elementary schools, &c. A sum of 200,000*l.* is again provided for special grants to certain necessitous local education authorities. The estimate for scientific investigation, &c., includes a grant of 7500*l.* in aid of the expenses of the aeronautical section of the National Physical Laboratory, and a grant of 20,000*l.* in aid of the expenses of the British Antarctic Expedition of 1910.

THE following courses of free advanced lectures have been arranged by the University of London:—a course of five lectures on "Fertilisation and Related Phenomena," to be given by Prof. J. B. Farmer, F.R.S., at the Royal College of Science, on Wednesdays at 5 p.m., beginning on April 27; a course of five lectures on "The Anatomy of Plants in Relation to External Conditions," to be given by Mr. L. A. Boodle at University College on May 26, May 30, June 2, June 6, and June 9, at 5 p.m. A course of three lectures on "The Geology and Geography of Charnwood Forest" will be given by Prof. W. W. Watts,

F.R.S., at the Imperial College of Science and Technology, on Mondays at 5 p.m., beginning on April 25. The lectures are addressed to advanced students of the University and to others interested in the subjects. Admission is free, without ticket.

THE difficulty of reaching the cultivator of the soil for any educational purpose has not as yet been overcome in any country, and certainly not here. Some interest, therefore, attaches to a scheme that has been at work in the West Indies for about eighteen months, and has proved so effective that it is to be adopted permanently. Courses for home reading are drawn up, divided into three parts, at the end of each of which are held examinations known respectively as the preliminary, the intermediate, and the final. The preliminary examination requires a general all-round education, and is dispensed with in the case of students who possess certain qualifying certificates. The intermediate examination requires such knowledge of the general principles of agriculture, and of planting work in particular, as might be expected from an intelligent overseer of a few years' experience, while the final examination reaches the standard necessary for a man capable of managing an estate. A leaflet is issued by the West Indian Agricultural Department containing a syllabus of the subjects necessary for each part, with hints as to what books should be read. In addition, the *Agricultural News*, the fortnightly paper issued by the Department, devotes nearly a page in each issue to notes bearing on the current work of the estate, thus giving the necessary practical illustrations of the general principles set out in the text books. A few questions are also set which students are advised to attempt. The Department, however, does not set up to act as a correspondence college and correct the answers to the questions. It is left to the student to find someone who will discuss his work with him and help him over those hard places where a man, reading on his own account without any assistance, inevitably gets stranded sooner or later. At first the officers of the Department gave a good deal of help by organising students' meetings where difficulties could be discussed; voluntary workers also came forward. The examinations are conducted by the staff of the Department, acting in conjunction with some of the planters. The intermediate and the final are essentially technical in their nature; the candidate is expected to be a better man at field or plantation work as a result of his reading, and he must demonstrate his superiority to the satisfaction of the planters on the examining board. In this way the interest and sympathy both of masters and of men can be enlisted, and both are brought to realise that the certificates awarded indicate increased efficiency on the part of the holder. Interest in the scheme is said to be spreading among the cultivators while the organisers have found certain modifications that will still further increase its utility. It will be carefully watched by those in this country who are engaged in elementary agricultural education.

THE National Union of Teachers held its conference this year at Plymouth during Easter week. Naturally, most of their discussion was confined to various aspects of elementary education, but other subjects of national importance were also considered. Mr. Marshall Jackman, the president, was chiefly concerned with a demand for more money from the Treasury for elementary education to relieve the financial straits in which many local education authorities find themselves. Mr. Jackman contended that we build Dreadnoughts regardless of cost, not because we want them, but because we feel the necessity of keeping pace with our neighbours. If we could have a similar cry in education to the Two Power standard cry for the Navy we should be able to do much for educational progress. He set out a national educational standard which he thought was worthy of this great Empire. Is it too much to demand that the educational opportunities for British boys and girls shall be no less than those for the children of any other nation? His new standard was that all forms of education should be as free to the British child as to the American child, the elementary schools of Britain should be manned by teachers no less efficient than those in the schools of Sweden, the classes of the schools in Britain should be no larger than those of De

mark, and the health of the children in this country should not be less cared for than that of the children in German schools. The care of adolescents came in for careful debate. Sir Henry Hibbert, chairman of the Lancashire County Education Committee, said the duty of providing further discipline and training for all children during the years which follow the day-school period is receiving attention in many countries, all of which seem to be moving towards three conclusions:—(1) that increased effort should be made by the State to compel local authorities to organise, according to the needs of different localities and of different trades, courses of instruction useful to any child, and so planned as to train them for healthy living and for the duties of citizenship; (2) that there should be a further limitation of the hours of juvenile labour; and (3) that all employers, Government as well as private, should be compelled by law to enable any persons of less than seventeen or eighteen years of age employed by them to attend courses of instruction, general or technical, for a specified number of hours per week at times during which the pupils would not be too tired to profit by the instruction. Dealing with the same subject, Miss Adler, of the London County Council, explained that the aim of the trade schools of the London County Council is not entirely to supersede apprenticeship, but to reduce the period of indenture, and to enable the lad to enter the workshop already equipped to take an intelligent interest in workshop processes, to handle tools effectively, and to be in a better position to learn by observation than the lad who enters the workshop direct from school. The development of handicraft side by side with the general intelligence is the primary aim of the trade school, and when this is possible on practical lines postponement of entry into the workshop is a distinct advantage, more especially when the trade side of the work is to some extent supervised by members engaged in the industry taught in the school. It was pointed out during the conference that the cost of compulsory attendance between fourteen and seventeen would be some 2,625,000l., and if the age were increased to eighteen 5,000,000l.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Microscopical Society, March 16.—Prof. J. A. Thomson, president, in the chair.—Miss L. S. M. Summers: Antipatharians from the Indian Ocean. Fourteen species were dealt with, including three which are new, viz. *Cirripathes indica*, *Antipathes salicoides*, *Pteropathes simpsoni*. In several cases the presence of well-preserved polyps made it possible to remove some of the doubts which Brook expressed in regard to various species. The paper referred also to certain peculiarities in the polyps and spines. The collections were made at Ilbo, in Portuguese East Africa, and in the Mergui Archipelago.—E. M. Nelson: The visibility of the tertiaries of *Coscinodiscus asteromphalus* in a balsam mount. The author directed attention to the continued improvement in microscope objectives, and particularly to a new $\frac{1}{4}$ -inch objective by Zeiss. Twelve years ago he received a slide of Nottingham deposit mounted in sulphide of arsenic, and he then saw, for the first time, the tertiaries in *Coscinodiscus asteromphalus*. He had had a balsam mounted selected slide of this diatom since 1876, and had tested hundreds of objectives upon it, but these tertiaries had never been visible. Recently he received from Messrs. Zeiss a long tube $\frac{1}{4}$ -inch apochromatic object-glass of N.A. 1.4, and it was tested on this balsam-mounted slide. The tertiaries which had for so many years eluded the grip of all kinds of lenses were conspicuous. This apochromatic $\frac{1}{4}$ -inch was more sensitive to tube length, stood a larger axial cone, bore a deeper eye-piece, and had sharper definition than any microscope lens he had previously seen.—A. A. C. Eliot Merlin: The measurement of the diameter of the flagella of the cholera bacillus prepared by Löffler's method. Slides of bacteria are prepared by Löffler's method to render the flagella more easily demonstrable, as the organism and its appendages are greatly distended by the process, thus rendering them comparatively coarse objects. Little has been attempted

as regards the measurement of these appendages since Dr. Dallinger read his paper on the measurement of the diameter of the flagella of *Bacterium termo* in 1878. The author of the paper obtained his results by what are termed extinction measurements, the resulting measurements being for the finest flagella $\frac{1}{64725}$ -inch and for the coarser $\frac{1}{62226}$ -inch. He checked these results by measuring, by means of a filar micrometer, the flagellum of a selected specimen, the measurement by this method giving a diameter of $\frac{1}{66756}$ -inch as against $\frac{1}{64725}$ -inch of a flagellum of approximately similar fineness measured by the extinction method.

Geological Society, March 23.—Prof. W. W. Watts, F.R.S., president, in the chair.—L. Moyses: Palaeoxyris and other allied fossils from the Derbyshire and Nottinghamshire Coalfield. After reviewing the bibliography of Palaeoxyris, the author records the finding of twenty-two specimens from Shipley Clay-pit (Derbyshire) and above 130 from Digby Clay-pit (Nottinghamshire), also several isolated examples from other localities in the district. He describes *Palaeoxyris helicterooides* (Morris), noting especially the presence of a "beak," which had not hitherto been adequately described. He then describes *Palaeoxyris prendeli* (Lesquereux) from Shipley Clay-pit, again noticing the formation of the "beak." The discovery of *Palaeoxyris johnsoni* (Kidston) from Digby is noted, and it is proposed that this fossil be removed into the genus *Vetacapsula*. The author also describes a specimen of *Vetacapsula cooperi* (Mackie and Crocker) from Newthorpe Clay-pit (Nottinghamshire).

CAMBRIDGE.

Philosophical Society, March 14.—Prof. Bateson, president, in the chair.—Sir J. J. Thomson: The cause of the phosphorescence of the glass in vacuum tubes when the pressure is not very low.—J. A. Crowther: Transmission of β rays.—J. L. Glasson: Secondary X-rays from metallic salts. These experiments show that the absorption coefficient of the secondary homogeneous X-rays from the metals of the chromium-silver group is unaffected by the combination of the metal with certain acid radicles. The only effect of the combination is the superposition of a small quantity of hard scattered radiation on the homogeneous radiation of the metal. Moreover, the valency of the element has no influence on the secondary homogeneous radiation from it. The absorption coefficient of the characteristic radiation from manganese is deduced from the absorption curve of manganese sulphate.—S. G. Lusby: Some experiments on ionisation in dried air. All the known properties of ions have been found to vary with the amount of moisture present in the gas experimented on, but in all cases the negative ion is the more susceptible. Hence it was thought that if the gas were dried, it should acquire a positive charge. The experiment was therefore tried, liquid air being used as the drying agent. On testing a stream of air which had been ionised and then dried, no indication of electric charge was detected. By using another method, it was found that both the positive and the negative ionisation are increased greatly by this drying action, but in an equal ratio, which in some cases amounted to ten. This was found to be due to decreased re-combination. The effect could be eliminated by previously filtering the air.

DUBLIN.

Royal Dublin Society, March 22.—Mr. R. Ll. Praeger in the chair.—Prof. T. Johnson and Miss R. Heneman: Agricultural seeds and their weed impurities; a source of Ireland's alien flora. The first-named author stated that as under the Weeds and Seeds Act for Ireland he had ceased to be responsible for the seed-testing station of which he had been director during the ten years of its existence (1900-9), the paper he communicated gave a summary of the purity and germination percentage of the 11,000 samples of seeds already tested, and of the weed-seeds found in these samples. Utilising the results of Dr. Stebler's investigations, he showed how many of the weed-seeds serve as source-indicators of the agricultural seeds sold. The paper contains also a list of casuals already recorded in the Irish flora, so far as these are traceable to introduction in seed. A list of 120 weed-seeds is given, 75 per cent. of which are the seeds of non-indigenous weeds.

PARIS.

Academy of Sciences, March 29.—**M. H. Poincaré** in the chair.—**Paul Sabatier** and **A. Mailhe**: The mechanism of the dehydration of alcohols by the catalytic action of various metallic oxides. The action of sulphuric acid and of metallic oxides upon alcohols at various temperatures is compared, and the possibility of the formation of a compound of the oxide and alcohol analogous to ethylsulphuric acid considered.—**M. Carpentier**: A description of a new electrical measuring instrument, the logometer.—**Charles Nordmann**: Remarks on a preceding communication.—**G. Donigès**: The detection of methyl alcohol in general, and especially in the presence of ethyl alcohol. The method, full details of which are given, is based on oxidation by potassium permanganate in dilute sulphuric acid solution. Formaldehyde is produced, and is detected by fuchsin decolorised by sulphurous acid.—**P. Yvon**: Aniline arsenyl tartrate. Details of the preparation and physical properties.—**A. Guilliermond**: New observations on the cytology of yeasts. The results of the experiments given are entirely opposed to the views put forward by Wager and Peniston.—**M. Dugast**: The presence of boron in Algerian wines. All the Algerian wines examined, of known origin and purity, were found to contain boron.—**E. Chuard**: A new method of treating for mildew by oxochloride of copper. The substitution of the oxochloride of copper for the mixtures of copper sulphate and lime reduces the amount of copper used to one-half.—**Maurice Gignoux**: The classification of the Pliocene and the Quaternary in southern Italy.—**Jules Welsch**: The formation of the Poitevin Marais and the separation of the "islands" of Ré and Oleron.

DIARY OF SOCIETIES.

THURSDAY, APRIL 7.

ROYAL INSTITUTION, at 3.—The Himalayan Region: Dr. Tom G. Longstaff.

LINNEAN SOCIETY, at 8.—Elm-seedlings showing Mendelian Results: A. Henry.—On the Foraminifera and Ostracoda from Soundings, chiefly deep-water, collected round Funafuti by H.M.S. *Penguin*: F. Chapman.

RÖNTGEN SOCIETY, at 8.15.—Some methods of using the Alternating Current Mains for Röntgen Ray Work: Dr. G. B. Batten.—Treatment of X-Ray Dermatitis by Radium: Mackenzie Davidson.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—The Progress of Electric Braking on the Glasgow Corporation Tramways: A. Gerrard.

FRIDAY, APRIL 8.

THURSDAY, APRIL 14, 1910.

THE CLAIMS OF LONG DESCENT.

Vorträge über botanische Stammesgeschichte, gehalten an der Reichsuniversität zu Leiden. Ein Lehrbuch der Pflanzensystematik. Zweiter Band, Cormophyta Zoidogamia. By Dr. J. P. Lotsy. Pp. 902. (Jena: Gustav Fischer, 1909.) Price 24 marks.

THE expectations aroused by the first volume of this work, which dealt with the Thallophyta, will not be disappointed by that now issued, in which are included the liverworts, mosses, ferns and fern-allies, and also the seed-producing plants that possess ciliated male cells. In its wide compass are thus at the one extreme types of a very low grade of complexity, while at the other stands Ginkgo, long regarded as a true conifer. The endeavour to trace the ancestry of the types in this range of forms raises many of the most interesting and suggestive problems in systematic botany, towards the answers to some of which much progress has been made in recent years.

The contributions to their solution have been made in a literature so scattered, and in so many languages, that much of what has been published is difficult of access, and is apt to remain unknown to students; hence the gain is great when it is collected, analysed, and presented in clear and systematic form, especially when accompanied, as it is here, with an excellent bibliography and ample references to the original sources of information. Such a work as this must necessarily be very largely a compilation if it gives an adequate statement of the present state of knowledge and of the explanations put forward upon many disputed questions; but the author has added to its value by discussing these questions and stating the reasons for and against the solutions advanced.

While indication of relationships and of lines of descent is, as the title of the book implies, a prominent feature throughout, its scope is much wider than this, so that it is an admirable handbook to the study of the structure and life-cycles of the groups discussed in it.

In a brief review it is not possible to note more than a few of the many questions that arise in the consideration of the plants included in this volume. These plants agree in showing a cycle in which there is a marked contrast between the gametophyte and the sporophyte, or the x- and the 2x-generations, as Dr. Lotsy prefers to express them; and they also have the archegonium recognisable, though obscured among the higher forms. The two great divisions of Haploidales and Diploidales, characterised by the dominance of the x- and the 2x-generations respectively, express the recognition that recent discoveries have shown clearly the intimate relationships between the ferns and the seed-plants. After discussing the hypotheses with regard to the origin of the Haploidales and Diploidales, the author supports the view that they are derived by independent lines from Algæ of the group Isokonta. As to the origin of the antithetic generations in the cycle, he holds that the evidence does not warrant a dogmatic conclusion; but

in discussing the homologies of leaf and stem in the Diploidales he inclines to Potonie's hypothesis that both represent specialised parts of a thallus, and may be homologous with one another. Among the Haploidales the evidence points more directly to the same conclusion.

The structure and life-histories of a typical moss and of a typical fern are set in contrast; and then follows a similar account of a very simple (? primitive) type of each, to ascertain in how far the supposed algal ancestry can be traced. Then follows a survey of the genera under each division, including every genus that shows features of importance or interest, morphological or biological; and not a few questions of wider than mere systematic value are discussed clearly and helpfully, as they arise in connection with certain forms, e.g. under Hepaticæ are discussed the suggestion that Anthoceros may represent a stage in the development of the sporophyte in Diploidales, the origin of the foliose habit, adaptations for economising water in various types, the influence of light on dorsiventral structure, &c. The wide range of structure and of adaptability among Hepaticæ is emphasised as in marked contrast to the relative fixity of type among the true mosses; but among the latter many features of biological import are duly noticed, such as the methods of vegetative multiplication, and their relation in frequency to the greater or less difficulty in securing the union of the male with the female cells.

The classification of the mosses into Acrocarpi and Pleurocarpi is held to be too artificial, as is also the importance attached to the rupture of the capsule in the normal manner by a lid, those forms in which the lid is not broken away being regarded as not forming a related group, but rather as aberrant from various families. Examples are quoted of very long-continued vitality in the spores of certain mosses, up to fifty years in a species of *Cedipodium*. The enlargement and flattening of the apophysis in *Splachnum*, and the growth of root-hairs from the seta in *Eriopus*, may be regarded as efforts on the part of the sporophyte to provide nourishment for itself; but they only emphasise the dependence of the sporophyte upon the gametophyte among the mosses.

In sharp contrast to them, in this respect, stand the vascular plants or Diploidales, although for a brief period, during early germination, the sporophyte fern is as dependent on the gametophyte for nutrition as is the moss-capsule. The dominance of the sporophyte becomes always more evident as the adaptation to life as land-plants becomes more complete, and as the dependence on surface-water to allow of fertilisation of the ovum is done away with, until in the Angiosperms it becomes difficult to trace the gametophytes with certainty, and the sporophytes appear to be themselves sexual, as was long the interpretation of the structure of flowers.

Dr. Lotsy gives a very helpful explanation of the discoveries that in recent years have thrown so much light on the affinities of the great divisions of the Diploidales, and have broken down the distinction between Phanerogamia and Cryptogamia, discoveries in which the English-speaking races have taken so great

a part. It is now evident that the tendency to retain the megaspore within the sporangium, and to continue to nourish the gametophyte and also its offspring, the sporophyte, through the sporangium until the young sporophyte is provided with sufficient food in reserve to enable it to begin life on its own account with a fair prospect of success, resulting in the production of the seed, has originated in widely different types, and therefore on independent lines. Thus the true significance of the seed, as an adaptation to secure the fuller possession of the earth's surface, and to escape the dangers of dependence on water for the fertilisation of the egg-cell, has become realised. A new era in botany opened with the recognition of the common ancestry of ferns and cycads, based on similarities in their structure, by the discovery that supposed ferns of the Carboniferous strata produced true seeds resembling those of cycads in important respects, and on the not less startling discovery, which we owe to Japan, of the ciliated male cells in the pollen of *Ginkgo* and of the cycads. Of these and other great advances in recent years, such as in the knowledge of the Cycadeoidea, Dr. Lotsy gives a very clear account, which should be most helpful to students.

The vascular plants possessed of ciliated sperms, the Zoidogamia, he divides into two great groups characterised by the sperm-cells, which possess two cilia in the Lycopodiaceæ and their allies, and many cilia in the Filicineæ and seed-formers. He points out that this agrees with the groups based by Lignier on the structure of the leaves. Heterospory has been attained independently in several lines of descent in both these groups, and is thus no certain proof of close relationship among plants in which it occurs. His arrangement is in several respects a good deal different from that in use in English text-books, both in the relations of the larger divisions and in such minor details as breaking up Hydropterideæ and placing Marsiliaceæ beside Schizaceæ, and Salviniaceæ beside Hymenophyllaceæ, among the leptosporangiate filices.

On similar grounds *Selaginella* is brought back to Lycopodiaceæ, while *Isoetes* is placed between the Equisetaceæ and Filices, because of its polyciliate male cells and of the development of its spores and embryo. The present state of knowledge with regard to the structure and life-histories of the Lycopodiaceæ and their allies is in striking contrast to that of not many years back; and of this advance the author gives a good account. The relations of the alliance to other groups can now be estimated in a truer light than was formerly possible. Though certain types within it had advanced far on the way to the formation of seeds, there is no clear evidence pointing to the descent from them of any existing seed-plants.

The lectures treating of the ferns and their allies are of very special interest, in view of the ever-increasing evidence connecting them with the descent of the seed-plants. While the progress during the past decade has been very great, and has revolutionised former beliefs, it has shown also that the production of seeds had already been attained at a period so far back in geological history as to make it very improbable that direct proof of the lines of evolution will

be obtained. But while great problems will probably remain unsolved in detail, the general trend of progress has become evident, and there is reason to anticipate that the rate of advance will not slacken; though it seems scarcely likely that there can be many future discoveries so startling as those already alluded to.

The grouping of the leptosporangiate ferns takes full account of Prof. Bower's researches on the sporangia. The eu-sporangiate types, like the leptosporangiate, are derived from the Primo-filices, by separate lines of descent. The Pteridospermeæ are probably more nearly related to Marattiaceæ than to any other existing ferns, but over a very wide gap. The concluding lectures of this volume treat of the Cordaitales, Bennettitales, Cycadales living and extinct, and Ginkgoaceæ. They present subjects of extreme interest, and of the utmost importance in tracing the development of the higher plants.

Those who read this volume will feel that while it demands close attention, and while some of the lectures are of value for reference on subordinate groups rather than for questions of wider interest, the work well repays the attention necessary, and that the aim, kept steadily in view, has been successfully attained, to supply an unbiased and worthy representation of what is at present known with regard to the groups of plants discussed. The information brought together within its compass has been gathered from a vast field; and the sources from which it has been taken are scrupulously indicated, as regards both text and the excellent and copious illustrations, which do much to aid the exposition, clear though that is. We cannot but feel that it is more useful in its present form, available to be read and re-read, than it could be as a course of lectures. It must prove a great boon to students desirous to obtain an adequate guide to the researches of recent years, in a form that can permit of use as a work of constant reference, from which they may gain wider views of the science of botany.

The third volume, on siphonogamous seed-plants, will be most welcome, though it can scarcely deal with subjects of such interest, or so full of the charm of advancing knowledge. The standard of the two volumes already published is a guarantee for the expectation that it will be a most valuable addition to every botanical library.

UTILISATION OF PEAT.

Commercial Peat: its Uses and Possibilities. By F. T. Gissing. Pp. x+191. (London: Charles Griffin and Co., Ltd., 1909.) Price 6s. net.

IN this volume on peat, which is a companion one to that published in 1907 by Messrs. Björling and Gissing, the author's aim is the description, from a commercial point of view, of the various processes proposed for the utilisation of peat.

In pursuance of this object Mr. Gissing describes fully the preparation from peat of alcohol, moss litter, and paper, the cutting and drying of peat, and the manufacture of press turf and of machine turf, but the greater part of the book deals with the products got by the destructive distillation of peat.

The book is clearly written, contains many interesting illustrations, and, when taken in conjunction with Messrs. Björling and Gissing's work, forms a very complete descriptive account of the peat industries. Occasionally, however, the author, carried away by his enthusiasm for the utilisation of peat, refrains from directing attention to the more obvious defects in some of the schemes put forward, and leaves the capitalist in ignorance of facts which might materially alter the latter's relations to the projected industries.

The many attempts made within the past ten years to utilise our peat supplies have proceeded in three main directions, viz. the conversion of peat into fuel, the manufacture of power gas from peat, and the utilisation of peat fibres for the manufacture of paper, alcohol, moss litter, &c.

The chief difficulties attending the conversion of peat into fuel on a commercial scale are the removal of the large amount of water contained in freshly cut peat and the increase of the low specific calorific power, i.e. the calorific power of unit volume, of the fuel. The removal of the water by mechanical methods (hydraulic pressure, centrifuging, &c.), and also its removal by artificial heating, have been shown again and again to be unremunerative, and no process in which any of these methods forms a constituent part can, with normal prices prevailing for rival fuels, be regarded as economically sound. The only method for removing the water which has proved commercially successful is the method of air-drying employed by farmers for the production of their turf.

The specific calorific power of turf can be increased by converting the peat into press turf or into machine turf, but the difficulty of drying the product in a moist climate like that of Ireland, and the high cost of transport, render it unlikely that turf will displace coal as a fuel from any districts other than those in the immediate neighbourhood of peat bogs.

The manufacture of producer gas and its employment in industries such as the fabrication of glass, as well as the production of power gas and the recovery of the ammonia simultaneously formed, may under carefully selected conditions be made remunerative, but peat cannot, under any conditions likely to arise in the near future, become so cheap a source of energy as coal at the pit-mouth in England.

It is unlikely that the conversion of peat fibres into paper or into alcohol will prove successful commercially. From one ton of anhydrous, light, surface peat, by hydrolysis about 0.28 ton of reducing sugars can be obtained, and if the latter were all fermentable they would afford about forty gallons of alcohol. If this were the average yield of alcohol from peat the process would be very remunerative, but, unfortunately, about one-half the amount of sugars in hydrolysed peat consists of pentoses which are not capable of undergoing saccharomycetes fermentation, and consequently the yield of alcohol rarely exceeds twenty gallons per ton of dry peat; if surface peat is not employed in the manufacture, the yield may fall so low as five gallons per ton. If the yield of alcohol from a given speci-

men of peat falls below sixteen gallons per ton, the manufacture of "peat spirit" will be unable to compete with that of "potato spirit" owing to the greater value of the by-products in the latter industry. The peat moss-litter industry, on the other hand, is from the commercial point of view the most flourishing of all the peat industries, and is likely to prove as remunerative to the capitalist in the future as it has been in the past.

HUGH RYAN.

THE HEALTH OF THE SCHOOL CHILD.

The Hygiene of School Life. By Dr. Ralph H. Crowley. Pp. xiv+403. (London: Methuen and Co., 1910.) Price 3s. 6d. net.

IN his preface to this work the author states that it was written while he was medical superintendent to the Bradford Education Authority, and that the conclusions arrived at and the measures advocated are based upon his own practical experience gained amongst the schools and school-children of that city. He furthermore states that the views expressed receive no added sanction from the fact that he now holds an official position in the Medical Department of the Board of Education. Although this may be so, it seems as if his present position is responsible (through the official non-committal attitude it has engendered) for the one outstanding deficiency of the book, namely, a lack of definiteness and of detail. For instance, one who consults a manual upon the hygiene of school-life might reasonably expect some definite directions upon the cleansing and disinfection of school premises; the measurements of seats and desks for children in different age groups, with the appropriate slope of desks for reading and writing purposes; the distances recommended between the hanging-pegs of cloak-rooms; but in these respects, as in so many others, he will find but generalities. Indeed, generally speaking, the work is sketchy, and requires the addition of fuller and often more definite information to become a useful addition to the already voluminous literature upon the subject of school hygiene.

It need scarcely be said that the matter given and the views expressed by one with the experience and knowledge of Dr. Crowley are sound, and that certain parts of the work reach a good standard of merit; more especially is this true of the chapters upon special groups of school-children. The chapter upon medical inspection of the child in the school is also very good, and it impresses upon the reader the fact that medical inspection, and all that it involves, has a part to play now and in the future, the importance of which can hardly be over-estimated. As Dr. Crowley states in his introduction, it is a service which stands out clear and well-defined, demanding of the medical men and women who perform it the highest qualifications and attainments. While essentially a part of the public health service, it is nevertheless a department which can never know its own full development until it recognises itself as a part of the whole public health service of the country, and links itself up and has an organic relation with that

service. Although it is some sixty years ago since a certain measure of medical inspection of school-children was initiated in Paris, and Great Britain has been so slow to adopt a provision the value of which has been appreciated by many other countries for many years, the work has been started in this country with such zeal and enthusiasm that we promise very shortly to have established throughout these islands a scheme which will compare favourably with that of any other country. But it is essential to the best results that there should be a better knowledge of the demands of school hygiene among medical men who are called upon to work in connection with the schools, and also among the teachers; and suitable manuals upon this subject are therefore of great value and importance. The present work is so suitable in many respects that it is to be hoped that in a future edition more explicit information upon many of the practical details of school hygiene, which are wanting in the present volume, will be included.

MODERN SCHOOL GEOGRAPHY.

- (1) *Narrative Geography Readers*. By G. F. Bosworth. Book i., pp. viii+133; book ii., pp. viii+145. (London: Macmillan and Co., Ltd., 1910.) Price 1s. each.
- (2) *A Systematic Geography of Europe*. By G. W. Webb. Pp. viii+96. (London: Methuen and Co., 1910.) Price 1s.
- (3) *Narratives Selected from Peaks, Passes and Glaciers*. Edited by G. Wherry. Pp. iii+156. (Cambridge: University Press, 1910.) Price 1s.
- (4) *Cambridge County Geographies: Cheshire*. By T. A. Coward. Pp. x+207+maps. (Cambridge: University Press, 1910.) Price 1s. 6d.
- (5) *An Elementary Practical Geography for Middle Forms*. By F. Mort. Pp. 91. (London: Blackie and Son, Ltd., 1909.) Price 2s.
- (6) *A School Economic Atlas*. By Dr. J. G. Bartholomew, with Introduction by Prof. L. W. Lyde. Pp. xii+64. (Oxford: The Clarendon Press, 1910.) Price 2s. 6d. net.

A SET of new school books in geography suggests the possibility of finding from an examination of their contents the main lines along which instruction in this subject is tending at the present time to crystallise.

With a single exception the books named above differ considerably from those in school use ten to fifteen years ago: they suggest development in three directions, the first being that of the story told to beginners, the others, for older pupils, being the scientific methods of actual investigation by the pupil from the raw material of geographical records, and of considering the results of special study as placed together in a monograph, if such a word may be used in this modest connection, or of considering the actual experiences described by the traveller.

The single exception, Mr. Webb's "Systematic Europe" (2), recalls the old type of text-book, with its tit-bit collection of facts, of which the following is a specimen:—"Elche is famous for its date palms" (p. 32). Less than one-fifth of the book is given to a

general survey of the Continent, and the remainder is a fairly systematic treatment of the separate countries. Many of the facts seem to be unimportant; others are such as a good pupil might reasonably be expected to find out for himself from a modern atlas, provided he had had some little training in investigation. The attempts in the large-type matter to trace causal connections are not always happy, as, for example, in regard to the Gulf Stream, which is described as washing the western shores of Scandinavia, and to the Föhn effect, which is called a wind.

The "Narrative Readers" (1) set forth, in the first place, facts concerning the lives of children in other lands, and from the stories of their habits and surroundings the author passes to the stories of such interesting things as the whale fishery, Captain Cook's voyages, or the mutiny of the *Bounty*. The child is frequently referred to an atlas, but it would probably be better if the reference were to a globe which could be presented as a model of the earth.

At a certain stage of development it is more important that the child should be able to do things for himself than that he should memorise facts presented to him by an adult; and it is probable that no school subject provides a means for work of this nature so easily and so universally available as geography, hence the development of practical work in this subject. For this the main requirement is a good atlas, and the Clarendon Press is to be congratulated that the first venture in the provision of an atlas is one so likely to be largely adopted as the one under review (6). The child who works through the ample supply of material in the spirit outlined in Prof. Lyde's introduction will be well equipped as a thinker in terms of geography. From the point of view of scientific accuracy it would perhaps be helpful if some numerical values were added to the statistical diagrams relating to the main products of economic importance, and also that the values given should be either triennial or quinquennial averages; possibly future editions will be improved in these directions. Many additional facts are given in the introduction in a concentrated and technical language, presumably for the benefit of the teacher.

Before such an atlas can be used the pupil should have had some preliminary training in the making of similar maps, and for this purpose are provided for schools those books of practical geography of which Mr. Mort's is one example. Although it deals with contouring, with climate, and with vegetation, this book illustrates markedly the indefiniteness of the boundaries of school geography, for some of the earlier work suggested should probably be called observational nature-study, while much of the plane-tableing is surveying work which would, to many teachers, appear to be beyond the scope of a school course. Mr. Mort's book is not entirely "heuristic," as he tells many facts which the pupil might be expected to find out for himself.

It is not possible in practical exercises of this nature to cover the entire ground of geographical studies, and therefore the pupil is provided with two other kinds of text for reference or special study. The first

contains narratives by actual travellers, such as those edited by Mr. Wherry (3); these can be used as school readers, or can be set for home reading; this particular set deals with early climbs in the Alps. The second kind takes the form of a special study of a limited area, and the volume on "Cheshire" (4) illustrates the way in which the pupil may be brought into touch with the work of a specialist; such books should be in the geographical reference library. These works appear to typify the best efforts of modern teachers of geography.

B. C. W.

ELECTRICAL ENGINEERING.

(1) *Electrotechnics*. By Dr. John Henderson. Pp. xiv+165. (London: Longmans, Green and Co., 1909.) Price 3s. 6d.

(2) *Practical Testing of Electrical Machines*. By L. Oulton and N. J. Wilson. Pp. vi+210. (London: Whittaker and Co., 1909.) Price 4s. 6d. net.

1) THE efficient organisation of students' work in an electrical engineering laboratory is a difficult task, and especially so with large elementary classes. Advanced students may be trusted with delicate instruments and left to arrange the necessary connections by themselves, they require little supervision, and as their number is small this is easily given. With elementary classes the case is different. It is obviously impossible to let all the men do the same tests simultaneously, since that would require multiplication of apparatus beyond the financial capacity of most institutions. Hence tests of different kinds must go on at the same time, and since the demonstrator cannot personally supervise every one of these different tests from its beginning, it is important that the students should get very clear instructions in print. It is also important so to arrange the tests that they shall, with students of average ability, take about the same time, and to arrange the work generally with the precision of a railway time-table, because otherwise students will drop out of their order and fail to get the full benefit of the course. All this, and the necessity to adapt the work to the class of students attending and to the equipment which happens to be available in any particular institution, tends to make the instruction somewhat cut and dried in character, and this is likely to detract from its educational value.

The author, who has evidently experience of these difficulties and the way to make the best compromise possible between conflicting requirements, has, in the third volume of this series of physical and electrical engineering laboratory manuals, given us an excellent guide to laboratory work of this kind. He does not believe in the use of special apparatus, but very rightly teaches his students to make the tests in the laboratory very much in the same way that they will have to adopt when they get into practical life, that is, by the use of ordinary commercial instruments. He also adopts the principle that tests must be so arranged that only two, or at the outside three, men are necessary for any one test.

The subject-matter is divided into three parts, which roughly correspond to the City and Guilds of London

syllabus for the "elementary stage" and the "ordinary grades" of direct and alternating current engineering. We thus get in the first part Ohm's law, the Wheatstone bridge, calibration of instruments, fuse testing, some simple magnetic tests, and experiments with a small motor. In the second part we come to heating of wires, potentiometric measurements, more advanced magnetic testing, characteristics of dynamos, secondary batteries, photometry, losses in dynamos, and so on. The third part deals mainly with the fundamental relations of alternating currents, graphic methods of representing these, and some very simple tests on alternators. Transformers and motors are not dealt with.

In an appendix are given mathematical and physical tables which will be found very useful, not only by the student, but also by the practical engineer. So far as the student is concerned, some of these tables should bring home to him a sense of reality of his work. Students are apt to consider their class-work as something purely scholastic and detached from practical life. If, then, a student, after having in his work found some physical fact such as the fusing current of a certain wire, the E.M.F. of a given cell, or the power per candle required by, say, an Osram lamp, and then turns to the tables at the end of this book to see how his determination agrees with the figures there given, he must get the impression that what he has done in the laboratory has practical importance, and this conviction will give him additional interest and pleasure in his work.

(2) This book is intended as a guide in testing electrical generators and motors. In the preface the authors point out that it is impossible to give "all the theory that the subject entails," and that the reader must therefore also consult some of the many textbooks. This is obviously right; nobody can expect to find in a book which is primarily an instruction how to test the whole of the theory of electrical machines, but some fundamental theories must be given, and in this respect the book falls short of what the reader has a right to expect. The authors give some sort of theory, but it is neither closely reasoned nor always clearly expressed. The latter defect may to some extent be due to their adoption of some terms which give one the impression of being a kind of technical jargon employed in a particular shop or laboratory, though not generally found in scientific books. For instance, if we are told to take a "locked saturation" it is not immediately obvious that we have to determine the relation between starting torque and voltage of an induction motor; nor is it very clear what a "pressed down reading on the scales with the power off" might mean. On p. 34 we read that "C.B. is the leakage current and proportional to the current in the motor." Further that it is "required to overcome the counter E.M.F. due to leakage."

These are of course merely unfortunate ways of expressing certain ideas which the authors have correctly in their minds, but it is irksome for the reader to have continuously to exercise his ingenuity in order to find out what it is the authors really mean. In some cases this task looks almost hopeless, as, for

instance, when on p. 7 we find that for a star-connected motor the "total current" is $\sqrt{3}$ times the current per phase, and on p. 8 we read that the "total current" is $\sqrt{3}$ times the "current per terminal." What the authors may mean by their term "total current" is not otherwise explained, and the reader can only surmise that it is merely a conventional way of introducing a current which is proportional to the line current. The introduction of such a conventional term is, however, quite unnecessary, as is also the introduction of the term "apparent efficiency" (p. 30), which has no physical meaning, since it is the ratio of voltamperes, which is not power, to watts, which is power. The authors also distinguish between "real horse-power" and "brake horse-power," and thus give the reader the idea that brake-power is not real power, whereas they merely mean to distinguish between the electrical power input and the mechanical power output of a motor. This is quite clear from the text, but why puzzle the reader by using new or misapplying old terms?

The efficiency tests described are all direct, that is to say, input and output are measured and their ratio calculated; the authors think this less inconvenient than some method of determining efficiency by the measurement of lost power, or, as they call it, the "loading back" method. This may be true so long as one has to deal with very small machines, but most practical engineers prefer to test large machines by some differential method. One counsel given by the authors should be followed in testing every kind of machine, namely, to plot results as the test proceeds, so that doubtful observations may be eliminated before the test is finished and the apparatus dismantled. The tests described comprise a 50-horse-power induction motor, a 500-kilowatt generator, a 300-kilowatt rotary converter, a 75-horse-power single-phase railway motor, a 450-kilowatt direct-current generator, a 40-horse-power direct-current motor, and an enclosed railway type of motor of only 12 horse-power. These tests are explained very fully, and the results are given in tables and curves, which are carefully compiled. The reader having once accustomed himself to the authors' peculiar nomenclature (such as "rack" for rheostat, and the terms alluded to in the first part of this review) will find no difficulty in following the sense of the text, and will derive some benefit from the book by following the examples given if he has to make similar tests.

GISBERT KAPP.

THE PHYSIOLOGICAL ANATOMY OF PLANTS.

Physiologische Pflanzenanatomie. By Prof. G. Haberlandt. Vierte neuarbeitete und vermehrte Auflage. Pp. xviii+650. (Leipzig: W. Engelmann, 1909.) Price 19 marks.

THE first edition of Prof. Haberlandt's well-known work appeared in 1884, so that (as the author points out) it has already reached a respectable antiquity, as the age of scientific text-books is reckoned. But, even before 1884, Haberlandt was beginning to be known for researches of a kindred sort, e.g. in the protective adaptations in seedlings

(1877), and on the relation between structure and function illustrated by the assimilatory tissues (1880). By persistent work in this general direction he has made himself the recognised authority on "physiologische Pflanzenanatomie." Haberlandt dedicated his first edition "mit dem Ausdruck freundschaftlicher Verehrung" to Prof. Schwendener.¹ This was appropriate, because it was Schwendener, in his celebrated work, "Das mechanische Prinzip, &c.," who "raised anatomico-physiological research above the level of casual tentative experiment, and marked it out, once for all, as a definite department of science."²

Structure in relation to function is an old subject of inquiry, but it was pursued on theological rather than on scientific lines before the publication of the "Origin of Species," and Haberlandt's work is the direct outcome of that book. At first, however, adaptation was principally studied in the external characters serving for fertilisation, dispersal of seeds, &c. The meaning of histological peculiarities was neglected, or strangely perverted, as, for instance, in the comparatively recent dogmas that vessels do not serve as water-pipes, or stomata for gaseous exchange. Schwendener's work showed, in the most unexpected and brilliant way, the value to the plant of such a neglected point as the sectional outline of its mechanical tissues. After this the study of adaptation could not be confined to obvious macroscopic points, and Schwendener's work led up to the classification of tissues according to their physiological character, which forms the basis of Haberlandt's book.

Since the first edition (1884), Haberlandt's book has flourished and increased, as may be shown by the simple process of counting the pages. Edition i. contained 398 pp.; edition iv. 650 pp. Edition i. had 139 figures in the text, and these have increased to 291. This represents the legitimate growth of the subject, and it is to be noted that Haberlandt, from the extent of his own work, is well fitted to make use of the researches of others. Huxley has well said that only a man who knows the raw material of science at first hand can judge of the amount of "speculative strain" that the elements of a given problem will bear. It is this sort of knowledge that makes Haberlandt an admirable critic and exponent of the work of others.

If we compare the present volume with the first edition, the most striking point in which the modern book differs from its ancestor is the presence of a chapter on sense-organs. Botanists will be glad to have, in a compass of 50 pp. or so, a full discussion of the scattered controversies on this subject. Haberlandt's statolith theory of the sense-organs for the perception of gravity, and of the lens-function of the epidermis in relation to heliotropism, are the most speculative of his views, and are by no means universally accepted, but the most sceptical can hardly refuse to admire the skill with which these exciting hypotheses are upheld.

F. D.

¹ The present dedication bears the additional words "on the completion of his 80th birthday."

² Haberlandt's preface to his first edition, p. viii.

OUR BOOK SHELF.

The Fauna of British India, including Ceylon and Burma. Edited by Dr. A. E. Shipley, F.R.S. Dermaptera (Earwigs). By Dr. Malcolm Burr. Pp. xviii+217; 10 plates. (London: Taylor and Francis; Calcutta: Thacker, Spink and Co., Ltd., 1910.)

THIS half-volume is the first addition to the "Fauna of India" published since the regretted death of Col. Bingham; and Dr. Shipley, the new editor, reviews the arrangements made for forthcoming volumes in progress.

Dr. Burr, since the death of De Bormans, has made himself the recognised authority on the small and hitherto somewhat neglected order Dermaptera or Euplexoptera, often treated as a family (Forficulidæ) of the Orthoptera, and is at present engaged on a monograph of the earwigs of the world, of which the present volume may be regarded as an excerpt.

It is not many years since the total number of Forficulidæ described from all parts of the world was less than a hundred. Earwigs are not insects that are assiduously collected, or always easy to find, if not specially searched for; but in the present work Dr. Burr enumerates 135 species for British India alone, divided into 51 genera, 14 subfamilies, and 5 families. He treats the earwigs as a distinct order, under the name Dermaptera.

The author's preface relates chiefly to types, and to the various sources supplying material for this work. By an oversight, the British Museum, to which Mr. Burr has always had free access, is not alluded to in this connection, though in the table of species at the end of the introduction a column is devoted to indicating those in the national collection. The main part of the introduction is devoted to structure and habits, and is of great value, and the bibliography is also tolerably full; but we notice one extraordinary error under Westwood—"Rözel's Himalayas" for "Royle's Himalayas."

The technical part of the work is executed in the usual manner of the "Fauna Indica." The appendices offer us instructions for collecting and preserving earwigs; abbreviations of authors' names; and a useful glossary of terms. Of the ten plates, the tenth only is in colour; and there are sixteen text-figures representing various structural details.

Longmans' Wall Pictures. Flowers, Butterflies, and Moths. By Archibald Thorburn. Ten plates, each plate 2s. 6d.; set of ten plates in portfolio, 1l. 10s.

Descriptive Notes for Teachers, for use with Longmans' Natural History Wall Pictures. Notes on Flowers. By C. J. Longman. *Notes on Butterflies and Moths.* By W. S. Furneaux. Pp. 30. (London: Longmans, Green and Co., 1910.) Price 6d.

THE attractive set of wall pictures published under the above title consist of ten coloured plates, reproduced from water-colour drawings by Mr. A. Thorburn. On each plate, measuring 18 inches by 14 inches—with the cardboard mount, 25 inches by 20 inches—two plants and two butterflies or moths are depicted. The series follows a monthly sequence according to the appearance of the butterflies and the flowering of the plants; one plate is allowed for April and May, and two plates for each month from June to September. So far as the plants are concerned, an ecological basis also exists; thus the April flowers, the primrose and bluebell, are denizens of woodland, the poppy and bluebottle are agrarian, and the purple loosestrife and water-mint are typical marsh plants. The butterflies represented are Fritillaries, Blues, Peacock, Red Admiral, and other common species. The pictures are very effective, as Mr. Thorburn has combined

artistic rendering and setting with correct form and colour of the plants; the reproduction, too, is fully satisfactory, so that they form a most decorative series, eminently suitable for display in class- or school-room.

The descriptive notes to accompany the plates are useful, especially the descriptions supplied by Mr. Furneaux of the caterpillars which are not illustrated. The botanical notes present the systematic position of the plants, but do not sufficiently emphasise the ecological aspect; there is also correction required in the explanation of radical leaves and flowers.

Formation of Character. By Rev. J. B. S. Watson. With a Preface by Rev. G. P. Merrick, and a Foreword on Industry by Andrew Whitlie. Pp. 115. (London: H. R. Allenson, Ltd., 1908.) Second edition. Price 1s. 6d. net.

THIS handy little volume consists of pithy and stimulating addresses on such subjects as courage, temperance, industry, reverence, and the like. The author is chaplain of H.M. prison at Brixton, and has had exceptional opportunity for observing the disastrous result of lack of moral discipline and deliberate character-training in youth. He is strongly of opinion that between instruction in "religious knowledge" and the usual branches of secular education, instruction in manners and morals is apt to be neglected. Mere stuffing with knowledge is not culture, and the "religious" knowledge is too often a dead and dry acquaintance with almost meaningless metaphysical formulæ. There is much to be said for the contentions of the Moral Instruction League. Character is the important thing—not creed or dogma.

The book is just the thing to put into the hands of boys and youths, and will be interesting and helpful to teachers also. It contains a short preface by the Rev. G. P. Merrick (formerly Chaplain-Inspector of H.M. Prisons), and a foreword on industry by Mr. Andrew Whitlie, of the Commercial Bank of Scotland, London. A thousand free copies have been distributed to sailors by the chaplain of the Port of London, thanks to the generosity of T.R.H. the Prince and Princess of Wales and other subscribers.

Simple Jewellery; a Practical Handbook dealing with certain Elementary Methods of Design and Construction, written for the use of Craftsmen, Designers, Students, and Teachers. By R. Ll. B. Rathbone. Pp. xiv+280. (London: Constable and Co., Ltd., 1910.) Price 6s. net.

THIS is a useful manual which cannot fail to prove of great service to amateurs. It is mainly devoted to describing the methods of designing and making gold and silver ornaments from grains and wire, both round and flattened, nearly a hundred illustrations of such designs being given. Artistic questions chiefly occupy the attention of the author, but we notice some judicious remarks on the employment of acids in "pickling," while the instructions in the methods of using the blowpipe in "soldering" are very detailed and practical, being based on scientific principles.

Le Tremblements de Terre. By Dr. G. Eisenmenger. Pp. 187. (Paris: F. Alcan, n.d.) Price 60 centimes. SOME recent earthquakes, such as those of San Francisco, Valparaiso, Messina, and Provence, are described in vivid and popular language. The phenomena of earthquakes, their classification, causes and distribution, and the possibility of predicting their occurrence, are briefly considered. A book so cheap as this, if the facts were accurately given, would be useful at a time when the interest in earthquakes has become general.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. No notice is taken of anonymous communications.]

Colour of Water and Ice.

I HAVE read with much interest Sir Ray Lankester's letter on the colour of water in NATURE of March 17. I remember discussing this same problem in the case of ice with Sir Joseph Thomson when we stood at the foot of the great glacier at Glacier, B.C., during the western excursion of the British Association last summer. The rich blue colour of the hard, clear ice was remarkable, even in quite small pieces. The same blue colour is noticed when surface-ice, which has been formed slowly by conduction, is taken out of the St. Lawrence River. The blocks lose their colour when they are exposed for long to the light, and especially rapidly when exposed to sunlight. Coloured sediment and air cavities in the ice detract from the colour. I am inclined to believe that the colour of ice is a real absorption effect, due to the large molecular aggregates forming the structure, which absorb the long rays, and not a "blue sky" effect, as I suggested after seeing the blue ice of the glacier.

In the case of water, all the physical properties indicate the presence of complex molecular aggregates in solution, which become gradually reduced in number as the temperature rises. Thus the variation of specific heat, of density, of viscosity, and compressibility, all disclose an effect due to a gradual diminution of the molecular aggregates. I believe these are the same as the ice molecules, and constitute the absorbing medium which gives water its blue colour. Sea-water is particularly blue, and here we probably have added the effect of the salt molecules, in addition to the fact that the water is very clear.

Mr. W. H. Sherzer has shown (Smithsonian Report, 1907) that the blue colour of the water and ice of the glaciers of the Canadian Rockies is a real absorption effect. The blue colour is increased by the presence of minute white sediment, but not by coloured sediment.

If it has not been already tried, it would be very interesting to see what effect temperature has on the greenish-blue light transmitted through very pure water. If the colour is due to the presence of ice molecules, it should grow less as the numbers are reduced. I cannot help thinking of the beautiful blue colour of liquid air as soon as most of the nitrogen has boiled away; if this were due to the presence of complex oxygen molecules, such as ozone, it would be somewhat similar to water.

Centre of Gravity of Annual Rainfall.

THE question whether Mr. Cook's suggestions in NATURE of March 31 have a practical value can be very simply settled. It is proposed to consider the month to month rainfalls at a place as a series of parallel forces, $p_1, p_2, \dots, p_{12}$, say, where the distance (X) from the beginning of the year of the corresponding "centre of gravity" is given by

$$X = \frac{p_1 + 2p_2 + \dots + 12p_{12}}{p_1 + p_2 + \dots + p_{12}}$$

Now, if we assign arbitrary values to any ten, say, of the p 's (and these ten p 's could be selected in sixty-six ways), then, the position of the C.G. remaining the same, we have obviously a single linear equation in two variables to give us the values of the two remaining p 's, and this equation can be solved in an infinite number of ways. Thus the same C.G. can be given by an infinitely varied arrangement of sizes of the p 's, and therefore its position gives no indication whatever of the monthly distribution of the rainfall of the places referred to.

To illustrate by three simple examples. The absolute value of the elements is of no importance, and taking for

NO. 2111, VOL. 83]

convenience a rainfall of 36 inches, we might have the three following distributions:—

	A	B	C
	in.	in.	in.
January	3	0	12
February	3	0	4
March	3	0	2
April	3	6	0
May	3	6	0
June	3	6	0
July	3	6	0
August	3	6	0
September	3	6	0
October	3	0	2
November	3	0	4
December	3	0	12
Total Rainfall	36	36	36
C.G.	6.5	6.5	6.5
Rainfall Moment	234	234	234

Thus A, B, and C have the same annual rainfalls, the same C.G., and the same "rainfall moment." The question whether or not the seasonal distributions correspond to those of actual places on the earth's surface is not to the point, though, as a matter of fact, C approximates to the typical Levantine curve.

Thus places with very different rainfall distributions may have the same C.G. and the same rainfall moment, and the proposed method of comparing the rainfalls of various places appears to have neither a theoretical nor a practical value. The method may possibly have a certain critical value in comparing the yearly variations at a particular place, where there is but little change in type from year to year, and especially in such a country as India, where the seasonal rainfalls are exceptionally well marked; but this seems doubtful, and in any case the method could be used only in conjunction with the actual monthly values.

Certain Reactions of Albino Hair.

UNDER this heading in NATURE of March 24 (p. 96) Miss Igerna Sollas referred to some experiments of mine upon the hair of albino rats, in which she failed to obtain one of the reactions described in my note (Proc. Physiological Soc., March 27, 1909). It is, of course, not improbable that different albino rats may carry different chromogens, and that some of them may lack the one which, when oxidised with H_2O_2 , gives a brownish colour. On the other hand, the failure may be due to the presence of some of the formalin, which may not have been completely washed away from the previous reaction.

There is one new observation which I should like to record here, since it bears upon the H_2O_2 reaction. The action of H_2O_2 is an oxidising one, and the production of a brownish tint may be interpreted as due to the oxidation of a colourless chromogenous body present in albino hairs. If this interpretation is right, other oxidising agents should produce a similar tint. During November of last year I casually placed two dead albino rats upon the top of one of my cages, these latter being kept out of doors. The rats were forgotten, and left exposed to the air for about a fortnight. During this interval the weather had been wet and warm for the time of year. Upon discovering them at the end of this interval, I noticed that on both rats the upper side, and part of the belly and back, had assumed the same sort of brownish tinge that H_2O_2 produces. The under side of both rats, which had been protected from the wet and light by its contact with the cage, was quite white. It thus seems possible to oxidise the chromogenous substance ostensibly present in albino rats by the oxygen of the air in the presence of continuous moisture. I do not think that light played much part in the reaction, since throughout this period it was very dull weather.

The mention of light brings me to another point in Miss Sollas's note. She says that prolonged immersion in the

formalin fluid results in the destruction of the colour. I am inclined to think that this destruction does not depend upon the solution, but is due to the action of light. I noticed the same thing in my experiments; but, in addition, I was enabled to observe—because I kept my rats in flat vessels standing on a *blackened* bench—that it was only the upper surfaces exposed to rather bright sunshine that thus faded. The under surfaces remained as brilliant a yellow as before. To confirm this conclusion I placed all my rats; still immersed in the solution, in a dark cupboard, and the partially faded colour somewhat returned, but not, I think, quite to the same intensity as originally. So long as I kept them in the dark the colour was retained. Whether this would be so indefinitely I should not like to say; but certainly it lasts for several months.

The yellow tinge assumed by some albino rats is, I think, not a phenomenon of light action, as Miss Durham, quoted by Miss Sollas, seems to imply, so much as one due to age. It is possibly a manifestation of diminished metabolism and lessened oxidation. Of the several hundred albino rats which I have bred, I do not remember any within their first year showing this yellow tinge, while it has been a frequent observation that old rats (after about the first year), though they were kept in semi-darkness, manifested a very obvious yellow colour. I do not wish to commit myself to this as a positive statement, for I made no scientific records of the matter. I am speaking from general impression alone; but it is certain there is a marked contrast between the pure white hairs of young rats, about six to eight weeks, and those of some twelve-month or older rats, all living under the same conditions as regards light.

With regard to Miss Sollas's experiments with the skins of guinea-pigs and with that of a single mouse, there are several considerations of interest that suggest themselves. Miss Sollas found, as I did, that albino mice give a negative result with formalin; but I subsequently found (*Proc. Physiological Soc.*, October 23, 1909) that if piebald mice are treated with 5 per cent. nitric acid in 75 per cent. *spirit* and are placed in the dark, in about five days most of the white areas of the pelage turn to a beautiful rose-pink colour. The same is true of albino mice. These experiments were performed in the summer; but during one cold week last winter I repeated the experiment on a single black piebald mouse, and the colour-reaction failed to appear. Upon placing the vessel containing the solution and mouse in an incubator at 102° F., the rose-pink colour appeared. The dependence of this colour-reaction upon temperature is confirmatory evidence that the phenomenon is one of ferment action.

It would be interesting to see if guinea-pig skins, which fail to respond to the formalin reagent, would do so with the nitric acid.

The Electrification of Insulating Materials.

SOME time ago, while endeavouring to get a trustworthy method of producing static charges in a humid atmosphere, I had occasion to experiment with celluloid. Rolled celluloid sheet with the surface burnished was found very suitable. If a "tassel" be made of this material by cutting up a small piece of thin sheet into narrow strips, then by simply placing the "tassel" on a table and stroking with the fingers, strong electrification is produced. On raising the "tassel" the strips diverge, and remain divergent in a most striking manner.

A further curious effect was observed, that if two narrow strips of celluloid were rapidly pulled between the fingers they were both electrified, one of the surfaces in contact being positive, the other negative. At first no consistent results were obtained that might lead to an explanation of the phenomenon; some found the top strip always positive, some the bottom strip when the pieces were held horizontally. Later, however, Mr. M. McCallum Fairgrieve, of Edinburgh Academy, noticed that the order of electrification depended on whether the strips were bent upwards or downwards when pulled in a horizontal direction through the fingers. This seems to be the true

explanation. Of the surfaces in contact, one is in compression, the other in tension; with celluloid the compressed surface is always negatively, the stretched surface positively, electrified. The effect is very apparent if the two strips are pulled slowly between the first finger and the thumb, and the strip in contact with the thumb will be + or - according as it is concave or convex to the thumb.

Of other substances investigated, paper, vulcanite, and shellac have the same property, and mica to a lesser degree.

I propose to investigate the phenomenon further, particularly with relation to electrification by compression and cleavage. In the meantime, I have made a small electrical machine in which three endless bands of celluloid run over pulleys. Suitable collectors are provided, and considerable + and - charges may be obtained. The charges are no doubt produced by the combined pressure and bending, as already explained.

Effect of Varying Temperatures upon the Colour and Growth of Fur.

THE following may be of interest to readers of NATURE. Some time ago an ordinary all-black cat was accidentally shut up in a refrigerating chamber on one of the Orient Line mail steamers when the vessel was in Sydney Harbour. The chamber was not opened until the ship was off Aden, which is about thirty-two days out. When the cat was brought out it was scarcely recognisable. Its coat had become long and thick, and the fur on its back was nearly white. It had lost one ear through frost-bite.

The change in the cat's environment from the intense frost of a refrigerating chamber to the intense heat of the Red Sea was accompanied by a rapid change in the cat's appearance. The heavy white coat rapidly fell out, and by the time the ship reached London the cat had practically regained its normal appearance.

I did not see the cat, but have inquired carefully into the statements, and have had their truth vouched for by one of the directors of the Orient Company.

April 6.

April Meteor Showers.

IN the present year there is likely to be a greater amount of meteoric activity about April 18-19 than, as might be expected, a few days later. There will then be an interval of quiescence until April 26. Between the latter date and the end of the month several important displays become due. The following are details of the most interesting showers, as calculated by the writer, that occur during the period April 12-30:—

Epoch April 19, 14h. 30m. (G.M.T.), shower of second order of magnitude. Principal maximum April 18, 22h. 18m.; secondary maxima on April 19 occur at 1h. 12m. and 9h. 25m.

Epoch April 27, 21h. 50m., shower of twenty-third order of magnitude. Principal maximum April 26, 16h. 26m. On April 26 there are also secondary maxima at 5h. 20m. and 18h. 55m., and another on April 27, 6h.

Epoch April 28, 11h. 15m., shower of fourteenth order of magnitude. Principal maximum April 30, 4h. 25m. There is a secondary maximum on April 28, 17h. 30m., and two others on April 29, at 12h. and 20h. 20m.

Epoch April 29, 12h., shower of fourth order of magnitude; the principal maximum becomes due about April 28, 12h.

While there are three meteor showers that fall between April 26 and the end of the month, there is only one of any importance during the period April 12-25. In some respects this earlier isolated display is the more interesting, however, owing to its being of greater intensity than the others, and of a somewhat different character.

Dublin.

JOHN R. HENRY.

THE BASUTO.¹

SIR GODFREY LAGDEN has given us, in these two volumes under review, a valuable history of the rise of the Basuto nation in the Switzerland of South Africa, under the leadership of a great man—Moshesh.

The Basuto, under the sway of this remarkable personage, were for the most part compounded of clans of the so-called Bechuana peoples, yet the root of their present national name—Suto (the Ba- is merely the plural prefix)—seems to have been derived from the same tribe or district of north-eastern Zululand (Ama-sutu, Usutu) as that which gave rise to the present royal dynasty of the Zulu people, to which Čechwayo belonged. No doubt it sent other enterprising adventurers farther west. By one of these was founded the Ba-suto clan from which Moshesh arose, in the circumstances cited by Sir Godfrey Lagden on p. 19. Moshesh was not directly descended from the stock of some bygone Zulu adventurer, whose tribal name—Suto or Sutu—had been adopted by these Bechuana people, but from a distant relative of the same racial origin whose ancestors had remained in the Amahlubi country to the south. The grandfather of Moshesh, however, had been adopted as a son and successor by Sekake, a Bakwena chief (apparently descended on one side from the original Umu-sutu). This adopted son was called Pete. He was succeeded by his own son, Mokachane, who was the father of Moshesh (this name as it stands means "a woman's garment" in the Se-suto language; but Sir Godfrey states that it is more probably an abbreviation of "Mosheshwe," which he interprets as "shaver" or "leveller"). The birth of Moshesh must have taken place about 1792, at Monkhoaneng, in Northern Basutoland.

About 1815, Chaka obtained complete control over the Zulu Kafirs of Zululand and Eastern Natal, and commenced that series of bloody wars in which, at the lowest possible estimate, a million Bantu negroes perished: wars which started a series of convulsions amongst the negroes of South Africa, that only came to an end by the death of Lobengula in 1894, the capture of Gungunyane by the Portuguese in 1895, and the complete subjugation (by force and by diplomacy) of the Angoni Zulus of Western Nyasaland by Sir Alfred Sharpe in 1906.

Wave after wave of Kafir or Zulu invasion of Basutoland took place after 1820, and, but for the mountainous character of Basutoland and the valour and genius for warfare of the Boers, not even Moshesh could have saved the remnant of the southern Bechuana peoples who gathered round him. But he found in Thaba Bosigo—the "Mountain of Night," under the shadow of Mount Machache, in north-western Basutoland—a stronghold from which no force—black or white—ever availed to dislodge him. The Zulu conqueror, Moselekatsi, might, perhaps, have succeeded (in spite of one severe repulse) in

taking Thaba Bosigo and establishing a secondary Zulu power in Basutoland (about 1832), but he could only have done this by surrounding the mountain and gradually starving out the Basuto clan. This purpose, even if he entertained it, was thwarted by the action of the emigrant Boers, who, by means of their firearms and system of laager camps (a defence of linked wagons), defeated Moselekatsi and drove him permanently beyond the Limpopo River.

Thus it was mainly the action of the white man which enabled the Basuto clan of the Southern Bechuana to expand into the Basuto nation. The emigrant Boers, after soundly thrashing Moselekatsi, saved from complete extermination the Bechuana peoples

Photo. by T. Lindsay Fairclough]

FIG. 1.—Fortified Cave at Lebise Masupha's Berea. From "The Basutos."

between the Kalahari Desert and Lake Ngami on the north and the Drakensberg Mountains on the south. The emigrant farmers themselves occupied, in the first instance, the less mountainous elevated plateaus to the north of the Caledon River.

But although Moshesh and his Basuto received the first missionaries (1833) gladly, and practically at no time put any opposition in the way of the spread of Christianity and education, they strongly objected to the Boers as settlers in what is now the Orange Free State. They wished to learn the wisdom of the white man, and, above all, to acquire his firearms and his horses (early in the 19th century they had begun that affection for the horse which has resulted in the re-

¹ "The Basutos; the Mountaineers and their Country." By Sir Godfrey Lagden, K.C.M.G. 2 vols. Vol. i., pp. xvi+338; vol. ii., pp. xii+339-690. (London: Hutchinson and Co., 1909.) Price 24s. net.

markable breed of Basuto ponies and the creation of a Basuto cavalry that has been, and will be, no negligible quantity in the forces of South Africa). Moshesh and his descendants, as soon as they saw a chance, entered into friendly relations with Moselekatsi in the far north, and his son Lobengula, with the kings of Zululand, and the more powerful clans of British Kaffraria and Northern Natal. In fact, no sooner were they relieved from the menace of Zulu conquest by the action of the Boers than they strove by many subtle means to push the white man as far away as possible from the centre of South Africa.

Their dislike of the British was quite as great as their dislike of the Boers. Between 1840 and 1852

Since 1884, when the native negro population of this State (which is nearly the size of Belgium) amounted to about 170,000, the total number of the Basuto has risen to nearly 400,000 at the close of 1909. Education, under French Protestant and British Wesleyan missionaries, has made considerable strides. The country, in fact, is so prosperous that it is becoming a factor of increasing importance in the problem of South Africa. Basutoland (the reviewer thinks) should have been made—if the advice of the one or two statesmen-governors of South Africa had been listened to in the first half of the 19th century—the Empire State of South Africa, the principal stronghold in all that region of the white race; and ample territories farther north or farther south might have been allotted *then* to the few thousand Basuto, who asked for little more at that period than peace, security, and an inalienable right to a reasonable amount of land. Now, as things are constituted, Basutoland is emphatically a black man's country,¹ and from Basutoland radiates a vigorous impulse which will go far towards securing for the black man eventual terms of equal partnership with the white in the administration of the southern half of Africa. Lest we should be petty-minded and regret this, let us turn our eyes to the recently explored regions of Northern Rhodesia, portions of Nyasaland and Katanga (greatly denuded of indigenous populations by various causes) which now invite settlement, almost by the million, on the part of adventurous white peoples.

The volumes reviewed deal mainly with the history of this interesting Basuto people. They are well illustrated by good photographs, and the numerous pictures of the Basuto types show clearly the three negro elements, imperfectly fused, from which this section of the Bechuana peoples has been built up. There is that of the Bushman (who immediately preceded the Basuto as the indigenous occupant), of the ugly flat-nosed type of Forest Negro or Pigmy (which reappears elsewhere in South Africa), and finally the typical Bantu strain from East Central Africa which imparts to many of the Basuto faces refinement of outline and considerable brain capacity. The scenery of Basutoland (the reviewer writes from actual experience) is amongst the grandest of the world's landscapes, and Sir Godfrey Lagden has taken care to emphasise this by "Wort und Bild." The second volume closes with serviceable notes on the Suto dialect, and appendices of great usefulness to the student of Africa. The book is, however, of very great general interest.

H. H. JOHNSTON.

[Photo. by Capt. French.

FIG. 2.—Ketane Falls and Gorge. From "The Basutos."

Moshesh and his chiefs made use of the British power to stave off a Boer conquest of their country. After that they attempted an aggressive attitude towards even the British, and inflicted on the soldiers of Sir George Cathcart a very serious repulse. From 1858 onwards they fought intermittently with the Orange State Boers (the Basuto being the aggressors), until at last, getting worn out in the struggle with these dogged white men, they invoked British protection in 1868. They were annexed as a Native State to the government of Cape Colony in 1872, but an attempt to disarm them brought on a fresh outbreak of warfare, in which the Cape forces gained no laurels and General Gordon's intervention proved futile. In 1884 Basutoland was disannexed, and has henceforth been directly controlled by the Imperial Government.

THE OCEANOGRAPHICAL MUSEUM AT MONACO.

AS stated in last week's NATURE, the inauguration of the Oceanographical Museum at Monaco took place on March 28, in the presence of representatives of the Governments and navies of France, Germany, Italy, Spain, and Portugal, and a great gathering of men of science of all nations, who were invited by the Prince of Monaco, and entertained as his guests in his ancient palace at Monaco and in various hotels in Monte Carlo. The inaugural fêtes lasted for four

¹ Note Sir Godfrey's remarks on this, p. 645, vol. ii.

days; they were planned on a scale of magnificence rarely attempted, and drew upon the resources of art in a manner which we believe has never been paralleled. It would almost appear as if the design were to show that science, no less than pleasure, was a fitting theme for the exercise of art as exemplified in painting, poetry, and music; and that, in any case, the dedication of a great international scientific institution, provided by the princely munificence of an individual, was no everyday matter, to be passed by unnoticed save by the specialists immediately concerned.

The inauguration was an arresting function, which could not fail to impress the most regardless pleasure-seeker in the gayest haunt of the Côte d'Azur with the thought that science, even in, perhaps, its least known department, was a thing of high importance. To us the fact that "someone had blundered" and no admiral of the British Fleet was there to join the high German, French, and Italian officers in offering a tribute to the scientific study of the sea was a cause of humiliation. It is little short of a disgrace that the country in which modern oceanography was created, and the navy the *Challenger* of which revealed the wonders of the ocean as a whole, were brought to the attention of the gathering only by the Prince's generous recognition in his inaugural address of British preeminence in oceanographical research, and in the name of the ship engraved on the façade of the new building. We know, of course, that the breach of international good manners was due to no intention on the part of the King or of the Prime Minister to inflict a slight upon a noble enterprise, but the effect was none the less deplorable, and on behalf of the British scientific public we desire to give expression to this feeling in the most emphatic way. The official representation of the Royal Society, the Royal Society of Edinburgh, the Royal Geographical Society, and the *Challenger* Society showed at least the good will and appreciation of British men of science.

It seems more appropriate to occupy this article with a short description of the museum itself than with details of the formal speeches at the ceremonial inauguration, the performance at the opera, the pageant in the harbour symbolising the landing of Hercules, mythical founder of Monaco, in a blaze of fireworks, and the concluding reception by the Prince in the Palace. One evening was devoted to a series of lantern demonstrations, by Lieutenant Bourrée, which proved of extraordinary interest on account of the cinematograph representation of the routine of work on the *Princesse Alice* in handling the various oceanographical instruments and appliances at sea.

The Prince of Monaco has devoted an increasing amount of time to deep-sea investigation since he commenced his observations on the Gulf Stream in the sailing-yacht *Hirondelle* in 1885, and, as a result of his work in that vessel, in the auxiliary steam-yacht *Princesse Alice*, and in his present splendid vessel *Princesse Alice II.*, he had accumulated, by 1898, so large a collection of natural-history specimens that he resolved to build a museum in which to house them. On April 25, 1899, the foundation-stone was laid on the southern face of the cliff which bounds the peninsula of Monaco, and the great building designed by M. Delefortrie has now been completed and equipped, and was formally inaugurated on March 28 this year. The first object has been greatly enlarged, and the Oceanographical Museum as it is established to-day contains more than the nucleus of a collection gathered from all investigators of all the oceans illustrative of the whole science of oceanography. On the face of the cliff the foundations of the museum

are almost at the level of the sea. Two storeys are built facing the sea, with the rock as their rear wall, and the third storey is on the level of the rock forming the ground-floor of the main frontage, which faces north. The material is the extremely fine-grained white limestone of the La Turbie quarries, on the mountains behind Monaco.

The ground plan of the principal floor includes a central hall twenty metres square, with a wing on each side forty metres long by fifteen wide, the whole frontage being a hundred metres. The decoration of the front of the building includes representations in relief of deep-sea invertebrates and fish, and the whole is crowned by the Prince's arms and a gigantic albatross and sea-eagle. The names of the *Challenger*, *Talisman*, *Valdivia*, *Hirondelle*, *Princesse Alice*, and other ships which have become famous in the annals of oceanography are boldly carved along the front. Two great groups of symbolic statuary flanking the immense window of the landing on the upper floor represent Truth unveiling the forces of the world to science, and Progress coming to the rescue of humanity. The roof of the central part of the building, eighty-seven metres above the sea, forms a meteorological observatory, and the main roof, five metres lower, forms an immense terrace, measuring a hundred metres by fifteen metres. The entrance-hall, floored with mosaics representing the *Princesse Alice* at sea surrounded by trophies of deep-sea fish, contains the two great stone staircases leading to the upper floor, and unobtrusive doors leading to the stairs by which the director's room, library, laboratories, workshops, and aquarium on the lower floors are reached. It opens into a large square hall, lighted at night by an immense pendant representing a medusa, the lights in which are so disposed as to bring out the anatomy with extraordinary distinctness. Four smaller lights are encased in models of radiolarians very exactly reproduced.

A marble statue of the Prince in yachting costume, leaning on the rail of his yacht, occupies the centre of the hall; this remarkably fine portrait, executed by M. D. Puech, was presented by a number of the sovereigns of Europe and other admirers of the Prince. Great doors to right and left open into the two wings of the building, each forming a lofty hall, lighted by windows along each side, which may be shaded or darkened as required. The western hall is at present fitted as a meeting-room for functions, and here the ceremony of inauguration and the banquet took place. The platform at the west end is surmounted by an immense painting showing the slaty-blue ocean heaved into a long swell, with the white form of the *Princesse Alice* in the background. Electric lights in clusters, representing seaweeds and marine animals, hang from the roof, and the ceiling is frescoed with views of the sea and ships.

The eastern hall is occupied by a collection of oceanographical apparatus and specimens of marine zoology, arranged in a provisional way. The collection includes several whale skeletons, Arctic and Antarctic seals, models of fish, and a vast number of specimens in preservatives. The labels are written in French, English, and German, and give sufficient details of the exhibits to enable a visitor to appreciate the remarkable character of many of the specimens.

On the upper floor, the central hall contains models of the *Princesse Alice I.* and the *Princesse Alice II.*, showing the arrangements for sounding and for working the zoological apparatus. There is a whale-boat exactly as used by the modern whaler, with the gun throwing the explosive harpoon at the bow, and the full equipment of harpoons, lines, and lances. The eastern hall on this floor will ultimately be devoted

to physical oceanography and to deep-sea apparatus. Here there is a great collection of dredges, tow-nets, showing the various devices for opening and closing at a given depth, the deep-sea traps with which the Prince has revolutionised the method of obtaining animals from the greatest depths, and many other appliances, either as used or in the form of models. At present a part of the room is occupied by a collection of specimens illustrating marine industries, such as fishing, sponge-gathering, collecting pearls, as well as the use of pearl-shell, coral, tortoise-shell, and similar products. The western hall is not yet arranged, but serves at present for classifying the various collections of mollusca, bottom-samples, &c., which are being dealt with.

The purpose of the museum is to have all the principal collections in duplicate, one set for exhibition, the other for purposes of study. The aquariums have already been utilised for the purpose of physiological and biological researches, and the little steam-vessel *Eider* is available for students to familiarise themselves with the methods of practical oceanography. This little steamer, of twenty tons displacement and sixty horse-power, is fitted for working to a depth of 2000 metres, and is being used for the detailed study of the portion of the Mediterranean in the immediate vicinity of the museum.

The Oceanographical Museum, under the direction of Dr. Richard, to whose admirable description of the building and the collections we are much indebted, is only one part of the Oceanographical Institute which the enlightened munificence of the Prince of Monaco has called into existence. With the object of arousing interest in scientific marine studies in France, the Prince started a series of lectures at the Sorbonne in 1903, and in 1906 he gave perpetuity to these courses of lectures by purchasing land which was much wanted for the extension of the university buildings and presenting it to the French nation, together with a building specially devoted to university instruction in oceanography. This building is now nearing completion, and will probably be opened in the present year, or at latest in 1911. Needless to say, the university and the French Government accepted the gift with lively gratitude. Three professorships have been created in connection with it, M. A. Berget having the chair of physical oceanography, M. L. Joubin that of biological oceanography, and Dr. P. Portier that of the physiology of marine life. The administrative council, under the presidency of the Prince, includes the names of several highly distinguished Frenchmen, but the committee for perfecting the institute is international, and includes representative oceanographers of all countries, Great Britain being represented by Sir John Murray, Dr. W. S. Bruce, and Mr. J. Y. Buchanan.

During the course of the Monaco gathering four important international committees met, each with the Prince as chairman, and, considering how his time was filled with State ceremonies and hospitality, it is only extraordinary enthusiasm, as well as most unusual physical strength, that enabled him to preside hour after hour, with unflinching courtesy and constant tact, over proceedings conducted in three languages. The committees were those for perfecting the Oceanographical Institute; for research in the Mediterranean, in which we understand that the Italian Government will take an active part; for research in the Atlantic, where international cooperation is hoped for, to be organised at a future meeting to be convened by the Oceanographical Institute in Paris; and, finally, for the preparation of a new edition of the Prince's bathymetrical chart of the oceans. It was decided in the new edition of this chart to suppress the indication

of the nature of the bottom, which is often fallacious, to add contour lines and certain physical features on the land, and to revise the terminology.

By his researches the Prince of Monaco has won for himself a place in the foremost rank of men of science, and by enshrining the results in the monumental buildings at Monaco and Paris he has invested his labours with permanent value for all time. His modesty and earnestness greatly impressed all those who took part in the proceedings here described, and, if a proof of this is demanded, it is enough to say that no one in authority mentioned the cost of the works, which is usually a prominent feature in the description of any benefaction.

THE RECENT GROWTH OF POPULATION IN WESTERN EUROPE.

IN his inaugural address as president of the Royal Statistical Society, delivered in November last and published in the *Journal of the Society* for December, Sir J. A. Baines deals in detail with the growth of the population of western Europe during the thirty years 1870-1900. The review covers the sixteen countries of western Europe properly so-called, excluding Russia, the countries of south-eastern Europe, and the "half-way" States of Hungary, Galicia, and Poland. In 1870 the population of western Europe so defined amounted in round numbers to 192 millions, a total which had increased by 1900 to 239 millions—an increment of nearly 25 per cent. But, as shown by the table below, the rate of increase was very different in different countries.

Country	Total percentage increase of population 1870-1900	Average annual rates of increase per thousand, 1870-1900		
		Natural	Census	Leakage
Sweden ...	23.2	11.7	7.0	4.7
Norway ...	28.9	13.9	8.5	5.4
Finland ...	53.3	13.9	13.2	0.7
Denmark ...	36.1	12.9	10.3	2.6
Holland ...	43.2	13.1	12.0	1.1
Belgium ...	31.3	9.8	9.6	0.2
Germany ...	38.1	12.5	10.8	1.7
West Austria ...	24.4	7.8	7.7	0.1
Switzerland ...	24.2	7.9	7.2	0.7
England ...	43.2	13.0	12.0	1.0
Scotland ...	33.1	12.8	9.6	3.2
Italy ...	21.9	9.4	6.6	2.8
Spain ...	12.8	4.9	4.0	0.9
Portugal ...	24.2	9.9	7.3	2.6
France ...	6.0	1.4	1.9	+0.5
Ireland ...	-17.6	6.1	-6.5	12.6
Total ..	24.6	8.7	7.4	1.3

France and Ireland are both very exceptional; the population of Ireland actually decreased by nearly 18 per cent., while that of France increased by 6 per cent. only. In the Scandinavian countries, the increase ranged from 23 per cent. in Sweden to 36 per cent. in Denmark and 53 per cent. in Finland; in the central group from 24 per cent. in western Austria and Switzerland to 43 per cent. in England and Holland. In all countries except France, the natural rate of increase, by excess of births over deaths, has been greater than the actual rate of increase, the average annual rate of increase by excess of births over deaths amounting (as shown by the second column of the above table) to 8.7 per thousand of the population, while the census only shows an average annual increase of 7.4 per thousand. The loss, or "leakage," has been greatest in Ireland, and next greatest in Norway and Sweden; in all countries save Italy the rate of loss was greater in the decade 1880-90 than in either the earlier or the later decade—in fact

nearly three times as great—but the continuous increase in emigration from Italy has placed it of recent years at the head of the emigrating countries (Ireland excluded).

In all the countries considered, both birth- and death-rates have fallen, and in the majority, especially those countries (as Holland, Germany, and Austria) in which the death-rate at the commencement of the period was high, the fall in the death-rate has exceeded the fall in the birth-rate, as shown by the table below; the natural rate of increase was therefore greater at the end than at the beginning of the period, in spite of the fall in the birth-rate. England is one of the exceptional countries, for the death-rate, even at the commencement of the period, was moderate, and the fall in the birth-rate has rather more than kept pace with the fall in mortality.

Country	Mean annual death-rate per 1000 ¹ 1871-1900	Mean annual birth-rate per 1000 ¹ 1871-1900	Decline per cent. in rates between 1871 and 1900	
			Deaths	Births
Sweden ...	17.2	28.9	10.4	11.2
Norway ...	16.8	30.7	4.1	2.3
Finland ...	21.0	34.7	11.2	13.0
Denmark ...	18.3	31.2	10.8	3.9
Holland...	21.2	34.3	24.3	11.4
Belgium...	20.8	30.5	15.0	10.2
Germany ...	24.8	37.3	18.3	7.7
West Austria...	27.6	35.4	13.3	6.5
Switzerland ...	21.1	29.0	19.1	8.7
England ...	19.6	32.6	14.9	15.5
Scotland ...	19.8	32.6	13.4	12.3
Italy ...	27.1	36.5	19.0	5.4
Spain ...	30.6	35.5	3.6	2.2
Portugal...	22.1	32.1	—	—
France ...	22.4	23.8	9.3	12.6
Ireland ...	18.2	24.3	1.1	13.2
Total ...	23.8	32.5	13.7	6.6

¹ Figures in italics are partly estimated.

The factors contributing to the fall in the birth-rate, which has recently attracted so much attention, are analysed in detail by Sir Athelstane Baines. For the most part it is clearly due to a fall in the fecundity of married women of reproductive age. The proportion of women of reproductive age to the population has in many countries (as in the United Kingdom) slightly increased, in other cases remained almost steady or fallen very little. The proportion of such women who are married, as shown by the table below,

Country	Number married per 1000 women aged 15-45 ¹		Legitimate births per 1000 married women, 15-45 ¹	
	1870	1900	1870-80	1890-1900
Sweden ...	420	411	278	268
Norway ...	436	418	302	301
Finland ...	502	471	285	292
Denmark ...	450	463	268	259
Holland...	440	446	345	321
Belgium...	409	471	338	252
Germany ...	471	504	319	285
West Austria...	448	473	295	271
Switzerland ...	419	442	288	266
England ...	496	469	292	235
Scotland ...	435	420	311	271
Italy ...	520	539	286	269

Portugal ...	420	452	—	259
France ...	531	552	195	159
Ireland ...	401	325	306	288
Total ...	490	500	276	249

¹ Figures in italics are partly estimated.

has fallen in all the Scandinavian countries save Denmark, but has increased in all the countries of the

central group, except England and Scotland. The births per thousand married women of fertile ages, on the other hand, have fallen in every country, with the sole exception of Finland (and perhaps one should add Norway), and most markedly in the central European group.

"The thirty years included in my survey," Sir Athelstane Baines concludes, "have been generally characterised by a moderate rate of growth of population, interrupted until towards the end of that period by considerable emigration, since reduced, except in one or two cases. People marry a little more than they did a generation ago, and, in most of the countries reviewed, they marry earlier; but the growth in the relative number of the married has been accompanied by a material decline in their output of children. Illegitimate unions, also, whether less frequent than before or not, at least contribute less to the tale of births. The community is therefore almost everywhere becoming an older one, with a gradually decreasing basis for the coming generation. Thanks to a general improvement in hygienic conditions, fewer succumb to disease, especially in early life, and the mortality having decreased more rapidly than the fertility of the population, the excess of births over deaths is relatively not below, but, on the whole, indeed, a little above that which prevailed at the beginning of the period."

PROF. HANS LANDOLT.

ON March 15, Geheimrat Prof. Landolt, the Nestor of physical chemists, passed to his rest, full of years and of honours. How few are left now of that ardent band who, in the early 'fifties, came under Bunsen's inspiration in romantic Heidelberg!

In a brief notice it is impossible to give an adequate picture either of the man or of his deeds. One is glad to think, however, that his devotion to science will be recognised in the memorial lectures by which the various societies strive to do honour to the memory of distinguished investigators.

Hans Heinrich Landolt was born in Zürich in 1831, and began the study of chemistry in the university of his native town. His *Wanderjahre* were spent in Breslau, where he graduated, in Berlin, where he studied under Rose and Mitscherlich, and, finally, in Heidelberg. His progress in the academic career was rapid. He became a Privatdozent in Breslau (1856), an extraordinarius professor in Bonn (1858), and an ordinarius professor in Bonn (1867). He then proceeded to the Technische Hochschule in Aachen. In 1880 we find him in Berlin, where he occupied the chair of chemistry in the Landwirtschaftliche Hochschule until, in 1891, he succeeded Rammelsberg as director of the second chemical institute of the university. When old age came upon him, his enthusiasm did not wane; he was active to the last.

Landolt's researches were by no means confined to one branch. In organic chemistry he studied, for example, compounds of arsenic and antimony, the action of potassium amide on various carbon compounds, and the chemical changes in the flame of coal gas. In inorganic chemistry he dealt with subjects such as phosphine, solid carbon dioxide, ammonium amalgam, thiosulphurous acid in aqueous solution, the interaction of bromine and nitric oxide. It is, however, on his pioneering experiments on molecular refraction and optical activity that his fame as an investigator will last for all time. With the exception of the contributions of Biot, very little of importance had been done on the measurement of the specific rotations of optically active substances until the field was taken up by Landolt in a series of papers which are models of exactitude. As a consequence of the experience he gained, workers in stereochemistry are indebted to him for numerous improvements in the technique of polarimetric observation.

He was engaged during the last twenty years of his life on the fundamental problem as to whether a change of mass during a chemical action can be effected by the ether possibly taking part, as it might be conceived to do by the appearance or disappearance of electrons or by the disintegration of atoms. The final result of these experiments, which demanded on the part of the manipulator the exercise of extreme patience, and involved the most exact measurement, was a confirmation of the law of the conservation of mass.

It may be added that Landolt's "Optisches Drehungsvermögen organischer Substanzen und dessen praktische Anwendungen" and his "Physikalisch-chemische Tabellen" (with Börnstein) are classical works of reference.

In a land where men of science are held in honour, it was natural that Landolt's services as a teacher and investigator should be appreciated to the full. Although he himself was the most unassuming of men, and although his work was not of the kind to bring him into the glamour of the footlights, it fell to his lot to receive an unusual number of high distinctions. He was held in esteem and affection by all who had the privilege of his acquaintance.

ALEX. MCKENZIE.

PROF. R. ABEGG.

PROF. RICHARD ABEGG, whose untimely death, in his forty-second year, was referred to in these columns on April 7, was one of the most distinguished representatives of the second generation of physical chemists. It was at the end of a ballooning expedition on April 3 that, whilst attempting to land, the balloon in which Prof. Abegg had journeyed from Breslau to Köslin caught in some bushes and tilted, with the result that he was thrown out and sustained a fracture of the skull, from which he expired in the early morning of April 4.

Abegg studied chemistry at Kiel, Tübingen, and Berlin, and devoted himself at first to organic chemistry. He took his degree, as a student of A. W. von Hofmann, in 1891, with a dissertation on amidochrysene, but the far-reaching results then recently achieved in the field of physical chemistry attracted him, and led him into post-graduate work in the laboratories of Ostwald, Arrhenius, and Nernst.

As assistant to Nernst in Göttingen from 1894 to 1899, Abegg devoted himself to most of the problems of physical chemistry. The action of kathode rays on various salts, the silver germ theory of the latent image, measurements of the depression of freezing points and the osmotic pressure of concentrated solutions, and electrochemical problems in turn claimed his attention, but his theory of electro-affinity, which was formulated along with Bodländer, marks his greatest achievement at this stage of his career. In 1899 Abegg went to Breslau University, where he was soon made an extraordinary professor. Here he continued his work, but a good deal of his time was absorbed by editorial duties. The theory of electro-affinity led to much work on complex ions, which was carried out in conjunction with pupils from all parts of the world, including England, Russia, Japan, America, and Australia, and this work in turn led to the formulation of his theory of valency.

Abegg acted as editor of the *Zeitschrift für Electrochemie*, and at the time of his death had edited about half of a "Handbuch der anorganischen Chemie." It is to be hoped that the work in connection with this Handbuch is so far advanced as to ensure its completion. In connection with analytical

chemistry, along with Prof. Herz, Abegg published his "Chemisches Praktikum," which marks an initial step in the application of the ionic theory to the early stages of qualitative analysis, a step which had been indicated by Ostwald in his "Wissenschaftliche Grundlagen der analytischen Chemie."

At the London International Congress of Applied Chemistry, Abegg was appointed on a committee to consider the annual publication of tables of physico-chemical constants, and he attended a meeting of this committee held in Paris last October. Last October Abegg was appointed director of the Physico-Chemical Institute at the new Technische Hochschule at Breslau, which is to be opened next October in the presence of the Emperor.

Finally, a word as to Abegg's genial personality. He made his students feel like colleagues, and was always available with suggestive advice. If we place Abegg in the second generation of physical chemists, he has done his duty by the third generation, and his death will be mourned as a personal loss in all parts of the world.

SIR WILLIAM BOUSFIELD.

ALL friends of education will deeply deplore the loss of Sir William Bousfield, who died on April 7, in his sixty-eighth year. Although he had received the ordinary Oxford education, Sir William Bousfield's wide culture and sound judgment enabled him to see the growing importance of practical and scientific education, and to form correct conclusions on the advice, which he eagerly sought and acted upon, of scientific men. Elected to the London School Board, of which he was a member for six years, in 1882, he took the deepest interest in all problems connected with the improvement of elementary education, and, during his membership, he was chairman of the special committee which was appointed to consider the question of manual training. That committee took evidence from a number of experts, and it was mainly owing to its recommendations that the City and Guilds of London Institute and the Drapers' Company subsequently provided funds for a great educational experiment in the provision of manual instruction in a certain number of schools under the direction of the Board, which resulted, not only in the general adoption of handicraft instruction for boys, but also of domestic teaching in all girls' schools. The success of this experiment was largely due to the efforts of Sir William Bousfield, who, when he ceased to be a member of the School Board, became vice-chairman of a joint committee, under whose direction these important experiments were successfully carried out.

Associated with the Worshipful Company of Clothworkers by family tradition, he was appointed, in the year 1887, a representative of that company on the council of the City and Guilds of London Institute. Although the Institute was exclusively concerned with the development of scientific and technical instruction, Sir William Bousfield's advice proved of the greatest possible service to the several committees of the Institute charged with the different branches of its work. It is, however, in connection with its technology committee—of which he was, for many years, first vice-chairman and subsequently chairman—that his loss will be most felt. In the solution of the many difficult problems with which the department of technology has had to deal, Sir William was able to render great assistance, and, of recent years, as chairman of the board of examinations of that department, which was charged with the preparation of schemes of instruction in every branch of technology, his help

was greatly appreciated. The continuous development of the work of that department, not only in the United Kingdom, but also in the colonies, was largely due to his clear judgment and full appreciation of the value to artisans and others of the technical instruction which was thus encouraged.

It is, however, in connection with efforts for the improvement of girls' education generally that Sir William's name will be best remembered. To the work of the Girls' Public Day School Trust, over which he presided, and which owed its success largely to his efforts, Sir William devoted himself without sufficient thought of the strain upon his health and energies. All who have had the privilege of acting with him recognise the extent to which his courtesy of manner and wise counsel enabled them to overcome difficulties arising frequently from conflicting interests. Of his services to the cause of charity organisation and social reform this is not the place to speak, but there can be no doubt that all those who are now occupied in the promotion and improvement of sound education in this country are the poorer for his loss.

NOTES.

WE announce, with deep regret, the death of Sir Robert Giffen, K.C.B., F.R.S., on April 12, at seventy-three years of age.

PROF. J. H. POYNTING, F.R.S., has been elected a member of the Athenæum Club under the provisions of the rule which empowers the annual election by the committee of nine persons "of distinguished eminence in science, literature, the arts, or for public services."

THE council of the Linnean Society at its last meeting decided to award the Linnean gold medal to Prof. Georg Ossian Sars, professor of zoology in the University of Christiania, in recognition of his eminent services to zoological science. Prof. Sars has been a foreign member of the Linnean Society since 1899.

MR. C. BIRD, headmaster of the Rochester Mathematical School, and the author of text-books on geography and geology, died on April 11 at sixty-seven years of age. He was three times president of the Rochester Naturalists' Club, and was a Fellow of the Geological Society.

A JOINT meeting of the American Society of Mechanical Engineers with the Institution of Mechanical Engineers will be held this summer in Birmingham and London. The meeting will open at Birmingham with a reception by the Lord Mayor of Birmingham and the members of the local committee on Tuesday, July 26. Following the meetings at Birmingham on July 26-28, the members of the American Society of Mechanical Engineers will be entertained in London. A *conversazione* will be held at the institution on the evening of July 28, and the following day will be devoted to the reading and discussion of papers in the morning and a dinner in the evening.

COLUMBIA UNIVERSITY, New York, is about to lose, by his resignation, the services of Dr. Charles F. Chandler, who has held a chair of chemistry in that institution since 1864. The completion of his academic career will be signalled by a banquet to which he will be entertained in the Waldorf-Astoria Hotel on April 30 by a number of the leading American chemists. On that occasion Dr. Chandler will be presented with a bronze bust of himself, and there will be created, as a permanent memorial, a Chandler testimonial fund in aid of the library of the Chemists' Club.

A NUMBER of changes in the organisation of the mines inspectorate and mines inspection districts have just been approved by the Home Secretary, who has followed the recommendations of the Royal Commission on Mines. In connection with these changes, the following appointments have been made:—Dr. W. N. Atkinson, divisional inspector for the new South Wales district; Mr. W. M. Pickering, divisional inspector for the new Yorkshire North Midland district; Mr. H. Johnstone, divisional inspector for the new Midland and southern district; and Mr. W. Walker, divisional inspector for the new Scotland district.

A GENERAL discussion on the constitution of water will be held on Tuesday, April 26, at the Faraday Society. Prof. James Walker, F.R.S., will preside. The discussion will be opened by Prof. Walden, of Riga, followed by the reading of short papers by Prof. P. Guye, Mr. W. M. Bousfield, K.C., and Dr. T. M. Lowry, and of communications sent by Prof. Nernst and Mr. W. Sutherland, of the University of Melbourne. In connection with the discussion, and particularly in honour of Prof. Walden, a dinner of the society will be held on the following evening, Wednesday, April 27, at the Trocadero Restaurant, London, W. The president of the society, Mr. James Swinburne, F.R.S., will preside.

THE progress of the recent eruption of Etna is shown in the following summary of Reuter telegrams from Catania:—*April 7.*—The eruption of Mount Etna continues. The stream of lava from Cisterna Regina is advancing slowly, while the stream from Monte Nocillo has considerably increased. It is now 300 metres in width. *April 8.*—One lava stream is increasing in speed, and has entered the Fusara district, travelling at about nine yards an hour. *April 11.*—Several of the Etna craters continue in active eruption. The flow of lava from the Fusara crater has ceased, but the streams from Monte Sona and in the Bottari plain are still advancing.

IN connection with the aviation week to be held in Verona in the first fortnight of May, it is proposed to organise a first International Congress on Aerial Locomotion. On the scientific side the movement has received the support of Profs. Angelo Battelli (Pisa), Giovanni Celoria (Brera Observatory), Giuseppe Colombo (Milan), Count Almerigo di Schio, Dr. Enrico Forlanini, Prof. Luigi Palazzo, Prof. Righi (Bologna), Prof. Vito Volterra (Rome). Hitherto there have been few opportunities of interchange of ideas between those interested in the theoretical and practical aspects of aerial navigation, and the proposed congress should afford a valuable opportunity for effecting a closer rapprochement between workers who are studying the problem from widely different points of view.

THE Sheffield meeting of the British Association will be open on the evening of Wednesday, August 31, when Prof. T. G. Bonney, F.R.S., will assume the presidency in succession to Sir J. J. Thomson, F.R.S., and will deliver an address. On Friday, September 2, the first evening discourse will be delivered by Prof. W. Stirling on "Types of Animal Movement." On Monday, September 5, the second evening discourse will be delivered by Mr. D. G. Hogarth, on "New Discoveries about the Hittites." The concluding meeting will be held on Wednesday, September 7. A reception will be given at the Town Hall by the Lord Mayor (the Earl Fitzwilliam, D.S.O.) on Thursday, September 1, and a reception will be given at the University on Tuesday, September 6.

number of garden-parties will be arranged, full particulars of which will be announced later.

THE Argentine Scientific Society is organising an International American Scientific Congress, to be held in the city of Buenos Aires on July 10-25. This congress will form one of the items of the programme arranged to commemorate the centenary of the revolution of May, 1810, which brought about the independence of the Argentine nation, as well as that of other nations of South America. Dr. J. F. Alcorta, President of the Argentine Republic, is the president of the congress, and Prof. N. B. Moreno and Mr. E. M. del Pont are the general secretaries. The work of the congress will be done in eleven sections, each having a number of subsections. The sections and the presidents appointed are as follows:—engineering, Mr. L. A. Huergo; physics and mathematics, Dr. M. R. Candiotti; chemistry, Dr. A. Quiroga; geology; anthropology, Dr. F. Ameghino; biology, Dr. A. Gallardo; geography and history, Dr. F. P. Moreno; economics and statistics, Dr. E. S. Zeballos; military science, Brigadier-General P. Riccheri; naval science, Rear-Admiral M. J. G. Mansilla; psychology, Dr. H. G. Piñero. All communications should be addressed, according to circumstances, to the president of the executive committee, Mr. L. A. Huergo, or to the president of the committee of propaganda, Mr. S. E. Barabino, care of the Argentine Scientific Society, 269 Calle Cevallos, Buenos Aires.

A "PHOTOGRAPHIC ARTS AND CRAFTS EXHIBITION" is open for this week only at the Royal Horticultural Hall, Vincent Square, Westminster. It is an excellent and representative show of modern photographic apparatus and materials, and includes a pictorial section, in which may be seen some of the finest portrait work, and examples of the applications of photography to various technical purposes, such as criminology, metallography, photomicrography in colours, &c. Demonstrations, lectures, and cinematograph shows are given from time to time. With regard to cameras, the chief fact that strikes one is the total absence of the large cameras that were familiar some years ago, often specially made for exhibition, and instead of them there are innumerable small cameras, some excessively small, and others of more moderate size, but all designed to give the utmost portability with efficiency. Messrs. Marion and Co. show one that takes plates $\frac{1}{4}$ inches by $2\frac{1}{8}$ inches, and folds into a rectangular block that weighs only 6 ounces, and is about half an inch thick, including the lens and shutter. Messrs. Adams and Co., Messrs. Houghtons, Messrs. A. E. Staley and Co., and other firms show cameras nearly, if not quite, as compact, and some of these are of a quality of workmanship that leaves nothing to be desired, and when provided with a first-class lens give pictures that will permit of considerable enlargement, so that a really efficient camera may now be the constant companion, in fact as well as in name, of naturalists and travellers, without the feeling that it is something extra to be carried. The present tendency to develop in tanks for predetermined times is obvious in the many models of apparatus for this purpose. The Standa Company has a new pattern in which the rack that carries the plates is hinged so that it will open out, and, if suspended by one end, allows free access of air to the surfaces of all the plates, a convenient method of drying them. Colour photography is represented by Messrs. Sanger Shepherd and Co., Messrs. Lumière, and Messrs. Wratten and Wainwright. Telephoto lenses are shown by Messrs. Dallmeyer, Messrs. Staley and Co., and others. There are altogether about

seventy firms exhibiting, excluding the pictorial section. A lecture on "Spirit Photography" is given three times daily, illustrated by some alleged "real spirit" photographs, as well as by examples of what is possible by well-known methods.

IN *L'Anthropologie* (January-February) Prince Georges Cantacuzene describes a collection of eleven skulls from a primitive cemetery at Corneto, near Civita-Vecchia. Of these he gives a detailed series of measurements, and the result of his investigation is to confirm the view that the old Roman race was composed of several divergent types.

IN the *National Geographic Magazine* for February Mr. Byron Cummings describes the great natural bridges in Utah. They are the result of a disturbance of the vast strata of red and yellow sandstone underlying that region, which left natural obstacles through which the rivers have worn their way. One of them is the Edwin Bridge, a graceful structure with a span of 194 feet and an elevation of 108 feet. Finer than this is the Augusta Bridge, combining massiveness with graceful proportions. It is 222 feet high and 261 feet between the abutments. Still greater, if not so well proportioned, is that which the Indians know as Nonnezoshi, or "Stone Arch," the greatest natural arch as yet found, measuring 308 feet in height and 275 feet between the abutments. In some places the process by which these natural wonders were formed may still be seen in action.

MAJOR STANTON, late Governor of Khartum, in a lecture recently delivered before the Colonial Institute, quoted in *Travel and Exploration* for April, notices a curious fact about the jerboa, or kangaroo rat. "It is found in considerable numbers in places miles and miles away from any water or even dew, and I was at a loss to understand how these little animals could exist through the ten months of drought. It appears, however, that after the scanty rains a small wild melon, of bitter taste but full of juice, flourishes in the desert. The jerboa, as soon as the melon is ripe, bites off the stem and proceeds to dig away the sand under the melon, so that it gradually sinks below the level of the ground. The constant wind soon covers it over with 6 to 8 inches of sand, which protects it from the scorching sun and from drying up. When all other moisture has evaporated, the jerboa goes to his larder of melons, and drinks the juice of these till the rains come on again. One jerboa will bury as many as forty of these little melons to last him through the dry season."

L'Anthropologie (Tome xx., No. 5) contains an interesting article by Dr. R. Verneau on three skulls discovered by M. Mansuy in the cave at Pho-Binh-Gia, in the oldest beds yet explored in Indo-China. This cave is situated 400 m. west of the village of the same name and 75 kil. north-west of Lang-Son (Tonkin). All three skulls are of the same ethnic type, and apparently belonged to a race of more than medium height. The most complete is that of a male, of which the mandible has also been obtained. A detailed description of the three skulls is given. The complete male skull is dolichocephalic (index 73.47), slightly phænozygous, with a rather narrow but well-curved forehead, somewhat prominent parietal protuberances, and the supraciliary arches are prominent only in the region of the glabella. The chief characteristic of the head is its disharmony, in which respect the old Indo-Chinese race approaches the Cro-Magnon race of the Reindeer period, the Grimaldi type of the mid-Quaternary age, and Lagoa Santa man, the most ancient type yet known in South America. The skulls of Pho-Binh-Gia are certainly not

Mongol. They seem rather to be representatives of the primitive Indonesian type, of which the Miao-tse and Khâs, as well as various peoples in the East Indian Archipelago, are descendants. The skulls appear to belong to the white rather than the yellow branch of the human race, which fact supports M. de Quatrefages's theory (which has been accepted by other students) of a white element having lived once in the continental regions of the Far East. The implements associated with these remains are of a Neolithic type; ornaments and pottery are rare. The absence of bones of large edible animals in the archæological layer leads to the conclusion that the ancient troglodytes of Pho-Binh-Gia were mainly vegetable feeders, but they also fed on fresh-water molluscs. It is proposed to make a fresh investigation of this important cave.

THE whole of part vii. of vol. cxviii., Abt. iii., of the *Sitzungsberichte* of the Royal Vienna Academy of Sciences is devoted to a relatively long article by Mr. O. Straeker on the plica longitudinalis of the duodenum, with its associated papilla, in man and the lower mammals, these remarkable structures being discussed in detail from the morphological, histological, and physiological standpoints in a number of species.

A SPECIAL exhibit has been made in the hall of the Natural History Museum of the mounted skin and skeleton of the specimen of the monkey-eating eagle (*Pitheophaga jefferyi*) recently living in the Zoological Society's Gardens, and the only example of its kind hitherto exhibited alive in England, and probably in Europe. This splendid eagle, it will be remembered, was discovered by the late Mr. J. Whitehead, and described, as a new genus and species, by Mr. Ogilvie-Grant in the *Ibis* for 1897, its nearest relative being apparently the South American harpy eagle (*Thrysaëtus harpyia*). Great credit is due to Mr. Rowland Ward for having made a complete mounted skin and skeleton from a single bird.

CONSIDERABLE interest attaches to a letter in the *Field* of April 2 from Mr. C. W. Stockley on rhinoceroses living for long periods in Somaliland without water. They inhabit certain parts of the Bur Dab, where, during the dry season, there appear to be no pools over a considerable area, the two nearest known drinking-places being thirty-three and forty-five miles distant. To these pools it is believed the rhinoceroses make only very occasional journeys. Such moisture as they require is obtained by eating the leaves of an aloe locally known as *dur*. Beisa oryx, on the other hand, maintain existence in the thirst-land by eating a small kind of gourd, called by the Somalis *unun*; but kudu, which likewise go without drinking for long periods in this country, browse on *dur*.

We have been favoured with a copy of an excellent little illustrated guide to elk and ptarmigan shooting in Norway, by Mr. Erling Hiorth, published, in English, at Christiania. Brief accounts are given of the haunts and habits of the two species, together with full information as to sporting localities, hotel-accommodation, tariffs, game-regulations, suitable clothing, &c. The pairing-season of elk in Norway commences about September 20, and the stags shed their antlers the following February, and begin to grow the new ones in May, which are clear of the velvet in August or September. The antlers begin to degenerate after the twelfth year. Highland elk are stated to differ from those of the plains by the slight development of palmation in the antlers. The calves, either one or two at a birth, are born in May.

WE have received vol. xii. of the third series of the *Anales del Museo Nacional de Buenos Aires*, the contents of which include Dr. Ameghino's paper on *Diprotomo*,

already noticed in *NATURE*, as well as several articles by Mr. Juan Brêthes on South American Diptera and Hymenoptera, and a long one by Mr. C. Spegazzini on Argentine Mycetozoa. In two articles from the succeeding volume (xx. of the complete series) Dr. Ameghino describes a young tapir-skull from Tucuman as a new species under the name of *Tapirus spegazzinii*, and likewise adduces evidence considered to prove the existence of a prelaetate dentition in the genus. The Tucuman tapir differs from *T. americanus* in its shorter and wider nasals. The presumed existence of a prelaetate dentition is afforded by the presence of small dental caps overlying some of the teeth of the milk-series.

THE alien problem has long since been acute in Great Britain in the case of human bipeds, and it promises ere long to become so as regards their feathered analogues, for the additions to the list of "British" birds are becoming appallingly frequent, the two latest, according to the April number of Witherby's *British Birds*, being the lanceolated warbler (*Locustella lanceolata*), a specimen of which was shot in Lincolnshire on November 18, 1909, and the Corsican woodchat (*Lanius senator badius*), of which an example was killed in Romney Marsh on June 20 of the same year. The former species breeds in Kamchatka, Japan, and Saghalin, and appears never to have been previously recorded from western Europe, so that it has nothing whatever to do with the British fauna. To exclude such stragglers from the British list seems impossible, as there is a gradual transition from these to species which are more regular visitors. At the same time, their inclusion is a great nuisance, as tending to swamp the proper fauna, and a satisfactory way of dealing with the difficulty is urgently required.

THE *Bulletin du Jardin Impérial Botanique*, St. Petersburg (vol. x., part i.), contains a list of fungi from the district of Moscow compiled by Mr. J. P. Petroff, and a note on the geotropism of some luffa fruits by Dr. N. Monteverde and Mr. V. Lubimenko. The latter refers to *Luffa acutangula* and other species, which it is stated acquire a positive geotropic tendency at the period when the fruits ripen with the purpose of casting the lid to allow of the escape of the seeds.

SYSTEMATIC articles in the *Kew Bulletin* (No. 2) are provided by a revision of the genus *Myxopyrum*, communicated by Mr. A. W. Hill, and a decade of new African determinations. Mr. C. E. Legat presents an account of a trek from Pietersburg in a north-eastern direction across the Zoutpansberg range in the Transvaal, undertaken with the object of studying the trees and shrubs growing in this little explored region. South of the range *Dombeya rotundifolia*, *Sclerocarya caffra*, and *Dichrostachys nutans* were frequently met with; *Copaifera mopane*, *Pterocarpus angolensis*, and *Adansonia digitata* were found to the north. A summary of Thompson's report on the forests of the Gold Coast directs special attention to arguments adduced as to the great influence of forests on physical and climatic conditions.

AN article on Chinese Rubi, by Mr. W. J. Bean, published in the *Kew Bulletin* (No. 2), gives particulars of some of the new species collected by Mr. E. H. Wilson. Their beauty lies chiefly in the stem and foliage, although one or two may, under cultivation, yield new fruits of good quality. *Rubus Veitchii*, noted as one of the most attractive, is a bush with purple stems and handsome pinnate leaves. *R. polytrichus* is a dwarf shrub without prickles, but densely clothed with hairs. *R. coreanus* is distinguished by its bluish-white stems, and *R. Parkeri*

is an elegant climber. The opportunity of studying these and other Chinese species is afforded by the establishment of a border in the gardens among the collection of the Rosaceae near the Pagoda.

A MAGNIFICENT botanical scene in the Lichiang range, situated in the big Yangtse bend in western Yunnan, is briefly described by Mr. G. Forrest in the *Gardener's Chronicle* (March 26). The limestone valley, at an altitude of 9000 feet, is the home of many Primulas, notably *Poissonii*, *denticulata* and *Forrestii*. The lower slopes of the range are covered with two dwarf evergreen species of oak and pines, and the cliffs are clothed with masses of Primula, *Cremanthodium*, *Meconopsis*, *Gesnera*, and other brilliant flowers. The pine belt ranges from 10,000 to 13,000 feet, where it gives place to rhododendron forest and scrub, and that in turn to Alpine pasture. The pine belt yields the finest and rarest plants, e.g. many species of Primula, Liliun (including *L. lophophorum*), Cyananthus, Codonopsis, and Androsace. The Alpine pastures also abound in magnificent plants, the most unique being two new densely-hirsute species of Saussurea, found on limestone rubble at a height of 16,500 feet.

REPORTS on various field trials with mangolds, swedes, and seeds hay have recently been issued from the Midland Agricultural and Dairy College. The trials are made on the usual lines, and aim at discovering the best varieties of the particular crops and the most suitable manures for use in the districts concerned.

ABOUT eight years ago sisal was introduced into British East Africa, and found to grow well. The quality of the fibre is satisfactory; its quantity is rather higher in the coast belt than in the highlands, but the cost of production in the latter case is less than in the former by reason of the better climate and cheaper and more regular labour supply. In the *Agricultural Journal of British East Africa* (vol. ii., part iii.) the whole problem is discussed, and although no definite conclusion is reached, there seems a prospect that the industry may be put on a sound basis.

It is not unusual in some districts to use sawdust as litter for cattle, and as it would then form a constituent of the manure produced, its nitrogen-content is a matter of some interest. Mr. Kinch recently examined a number of samples, and the results published in part v. of the *Agricultural Students' Gazette* are as follows:—

	Nitrogen	Mineral matter		Nitrogen	Mineral matter
Oak...	0.155	0.29	Spruce	0.14	0.71
Elm...	0.27	1.38	Larch	0.18	0.25
Ash...	0.29	0.68	Red pine...	0.30	0.33

These figures refer to the dry matter. In its ordinary state sawdust might be supposed to contain about 10 per cent. of water, in which case the mean nitrogen content is about 0.2 per cent.

MESSRS. PEARL AND SURFACE have issued a further instalment of their applications of correlation methods to poultry problems as Bulletin No. 168 of the Maine Agricultural Experiment Station. The fertility of the eggs, measured by the percentage of infertile eggs, does not appear to be inherited and is to a large degree influenced by external circumstances. On the other hand, the "hatching quality" of eggs, measured by the percentage of fertile eggs hatched, is a character of altogether different nature, being innate, constitutional, and inherited. It is, however, adversely affected by heavy winter egg production, whilst fertility is not. The two characters are not entirely unconnected; there is a small but sensible correlation between them, and a hen the eggs of which run high in fertility

will also tend to show a high hatching quality. Both are adversely affected by bad conditions of housing.

In a lecture given at the Farmers' Club on February 28, Mr. W. Herrod said that the usefulness of the bee in connection with agriculture had not been recognised by farmers in this country until recent years, and even now many looked upon bees as they did on wasps, as insects to be avoided. In some countries the bee was rightly held in high esteem for its usefulness in the production of seeds and fruit. Most plants depend on insects for fertilisation, although in some it is done by the wind. Amongst insects, the whole family of bees are of the greatest use; next come butterflies and moths, while flies even do their share of the work, but it is more especially the hive-bee that is the blossoms' partner, by carrying the fertilising dust from one flower to another. After describing the inhabitants of the hive, Mr. Herrod mentioned how the workers collect the nectar and carry the pollen from one plant to another. He then quoted Darwin, who found that twenty heads of Dutch clover yielded 2290 seeds, but twenty other heads protected from bees produced not one. Then 100 heads of red clover produced 2700 seeds, but the same number of protected heads produced not a single seed. He also mentioned experiments made in America which tended to show the great advantage gained by the fertilisation of clover by bees. That bees are useful to the farmer even with ordinary farm crops, and that some farmers realise this, is proved by the fact that hives of bees are carried into bean-fields just after horse-hoeing, and the plants are about to bloom, so that they may be close to the crop to carry out the work of fertilisation.

PROF. GRENVILLE COLE has issued a description of the raised map of Ireland contained in the National Museum of Science and Art, Dublin. It is at once concise and interesting, and, even without the aid of the raised map to which it refers, may be read with profit by anyone requiring a short but comprehensive review of Irish geological history. The development of the surface features of the country as dependent upon geological events is followed from Archæan times. It is enjoyable reading throughout. The illustrations are good. Some are old friends, but are not the worse for that. All are well chosen.

THE records of horizontal pendulums frequently show series of small oscillations which, in their brief period and long continuance, are quite distinct from those produced by distant earthquakes. In previous papers Prof. Omori has established the remarkable facts that the mean periods of the principal groups of pulsatory oscillations are 4.4 and 8.0 seconds, and that they are approximately constant all over the earth. He has recently returned to the subject in an interesting report (Bulletin of the Imperial Earthquake Investigation Committee, vol. iii., No. 1; Tokyo) on the oscillations observed in the Japanese islands of O-shima and Hachijo, and in two neighbouring districts of Tokyo. The oscillations, he finds, occur more or less at all times on extensive quaternary plains and on large alluvial valleys, but very seldom, and only to a slight degree, at places on granite and Palæozoic rocks. In the islands the oscillations are of frequent occurrence, and their mean period is, as a rule, 4.3 seconds. At Hongo, in Tokyo, three periods exist, with mean values of 2.9, 4.5, and 7.5 seconds, but those with a period of 4.5 seconds occur four times as frequently as those of the longer period. The approach of a deep barometric depression is invariably accompanied by the production of marked oscillations which have a mean period of 4.5 seconds.

Similar instruments installed in two districts of Tokyo, 2.29 km. apart, one on high and hard ground, the other on low and very soft ground, showed that the pulsations at the two places differed not only in phase, but also in their mode of grouping, while the mean period and amplitude were nearly the same.

BULLETIN No. 405, issued in 1909 by the United States Geological Survey, consists of a full account of the prolonged and exhaustive investigations carried out by Dr. W. F. Hillebrand and Dr. W. T. Schaller upon the chemical and physical properties of the remarkably interesting series of mercuric minerals, viz. kleinite, montroydite, terlinguaite, eglestonite, calomel, and native mercury, occurring at Terlingua, Texas. Of these, all, save the last two, are minerals which were first discovered and are as yet known only at this locality. Montroydite, terlinguaite, and eglestonite were first described by Prof. A. J. Moses; he noticed yet another possibly new mineral, but had not at his disposal sufficient material for its determination. The outstanding mineral was subsequently studied by Prof. Sachs, who gave it the name kleinite, and announced it to be an oxychloride of mercury with the formula $\text{Hg}_2\text{Cl}_2\text{O}$. One of the most interesting results arising from Dr. Hillebrand's analyses is to show that the mineral has a more complex composition, and is, indeed, a unique example among minerals of the mercury-ammonium group of salts. The precise nature of the molecular constitution, however, still remains uncertain, and it is not known what part is played by the small but varying amount of water present; the mineral may possibly be a mixture of the chlorine compound NHg_2Cl with other salts of mercury. The homogeneity above 130° and the heterogeneity below that temperature, as revealed by the optical characters, show that kleinite must have been formed at a relatively high temperature. Careful tests failed to reveal the presence of nitrogen in any of the remaining minerals, but Dr. Hillebrand found that the formula for eglestonite should be $\text{Hg}_2\text{Cl}_2\text{O}$, and not $\text{Hg}_2\text{Cl}_2\text{O}_2$, as deduced by Moses from McCord's analyses. Dr. Schaller's careful goniometric examination confirmed the fundamental constants and the symmetry already found by Prof. Sachs for kleinite and by Prof. Moses for the other minerals, but added enormously to the number of forms discovered. Dr. Schaller, who is evidently a whole-hearted disciple of Prof. Goldschmidt, based his discussion of the forms on the harmonic law enunciated by that versatile crystallographer.

THE meteorological chart of the North Atlantic Ocean for March, issued by the Deutsche Seewarte, contains an account of the second attempt at utilising wireless telegrams for weather forecasts. The experiment was made in August and September, 1909, and the district of observation was restricted to 10° - 30° W. longitude. The results tend to show that, so far as Germany is concerned, it is doubtful whether practical use can at present be made of the telegrams. The Seewarte considers that further study of the connection between the weather of any particular day in Germany and the preceding distribution of pressure over the ocean, and especially of the tracks taken by barometric depressions, is primarily necessary, and that this study can best be done by an examination of the daily synoptic charts which have been published for many years by the Seewarte and the Danish Meteorological Institute. We believe that similar telegrams were forwarded to the London Meteorological Office; the results, so far as this country is concerned, will no doubt be given in the committee's next annual report.

BULLETIN No. 36 of the University of Illinois consists of a paper on the thermal conductivity of fire-clay at high temperatures, by Messrs. J. K. Clement and W. L. Egy. The fire-clay specimens are cylinders 40 cm. long, 12 cm. in diameter, with a hole through the centre 3.5 cm. in diameter for the reception of a heating coil of nickel wire wound on a porcelain tube. The cylinders are further provided with two long holes 3 mm. in diameter parallel to the axis and extending to the central plane. Through these pass the platinum-platinum-rhodium thermocouples, by means of which the temperatures at two points of the central plane are determined. The specimens are enclosed in a fire-clay furnace, which has an internal diameter slightly greater than the external diameter of the specimens. The heating current is measured by means of a Weston voltmeter and shunt, and the thermocouples standardised by means of zinc, silver, or copper freezing in a carbon crucible in a special furnace. The electromotive force of the couple is measured by potentiometer and galvanometer. Two samples gave constant heat conductivities of 0.0026 and 0.0036, respectively, between 300° C. and 800° C., one other increased from 0.0021 at 300° C. to 0.0023 at 700° C., while a fourth increased from 0.0024 at 400° C. to 0.0026 at 800° C.

An illustrated article on the Royal Liver building, Liverpool, appears in the *Builder* for April 9. With the exception of the outer curtain walls, the building has been constructed entirely in ferro-concrete on the Hennebique system. Mr. W. Aubrey Thomas was the architect, and Messrs. L. G. Mouchel and Partners prepared the details of the ferro-concrete work. The building is 301 feet long by 177 feet 6 inches wide, these dimensions continuing up to the main roof at a height of about 170 feet above street-level. The domes surmounting the main towers are 29 feet above street-level, the extreme height from foundation-level to the topmost point being 360 feet, about the same as that of St. Paul's Cathedral. This huge building has eleven storeys up to the main roof, and six storeys in each main tower. From the structural point of view the building is essentially a monolith. Each floor was moulded at the same time as the corresponding columns and beams, so that the men engaged in setting up the framework of the next storey had the advantage of a continuous floor for the conduct of operations. The granite curtain walls constituting the exterior sheathing of the building are nowhere more than 14 inches thick, the weight being taken at each storey by lintels forming part of the general framework.

THE first of a series of illustrated articles on the construction of aeroplanes appears in the *Engineer* for April 8, and deals with the Farman biplane. This machine has the distinction of being the first to combine the rear planes for steadying purposes with ailerons or fins for obtaining lateral stability. Mr. Farman began his career in aviation as pilot of a Voisin biplane, a machine which depends for stability on its cellular construction. Farman drifted from the cellular aeroplane, and adopted the system of manual control which in various forms is now almost general. In the new Farman machines the planes have a supporting surface of 48 square metres. The older types have two planes of the same length, whereas the new machines have the lower plane shorter than the upper, the lengths being, respectively, 23 feet and 36 feet. The width and the height between the planes are equal, being each 6 feet $2\frac{1}{2}$ inches. Both ash and poplar are used in the construction. Most Farman biplanes are fitted with the rotary Gnome engine. A feature of the article is the numerous clear drawings of details given.

OUR ASTRONOMICAL COLUMN.

APRIL SHOOTING STARS.—Mr. Denning writes:—"The gibbous moon will be present in the sky during the ensuing return of the April Lyrids, so that a conspicuously visible display can hardly be expected. The night of April 21 will probably be the time of maximum, but nothing can be definitely predicted as to the strength of the coming shower. It seems to vary from year to year in an irregular manner, and has seldom presented a rich display comparable with that of the August Perseids.

"In 1909 there were few of the April Lyrids visible, though the skies were very clear on the important nights of April 20 and 21.

"The shower is, however, a very brief one, and often evades English observers by occurring in the daytime or at a period of cloudy weather or bright moonlight. It is a system which certainly requires much further observation, though it seldom provides us with a spectacle of abundant and attractive character; but it may return at any time and present a repetition of the splendid shower witnessed in 1803, so that it should be carefully watched every year."

HALLEY'S COMET.—The Cape Town correspondent of the *Daily Mail* announces that Halley's comet was observed, after its conjunction with the sun, at the Cape Observatory at 5h. 50m. a.m. on April 8. The comet was visible for ten minutes before becoming lost in the increasing daylight, and is reported as being brighter than when seen in February. The comet was observed at the Vienna University Observatory shortly before 5.0 a.m. on April 11, and was seen also at the Perth Observatory, Western Australia.

In No. 421 of the *Observatory* (p. 182) it is suggested that, as Dr. Wolf saw the comet as a naked-eye object on February 11, the estimated magnitude (9.0) given for the end of February must have been far too low; on the assumption that the brightness varies as $1/r^2 \Delta^2$, the comet should be at least as bright as the first magnitude when near the earth on May 20.

The question of the comet's brightness during May is also discussed by Dr. Ebéll in No. 4400 of the *Astronomische Nachrichten* (p. 140). Taking the recorded magnitudes, at various intervals from perihelion, during the apparition of 1835-6, and comparing them with those already recorded for the present return, Dr. Ebéll finds that the apparent magnitude at the time of greatest brightness, May 21, may be about -1.7, or about equal to that of comet 1910a at its perihelion. On this basis the present magnitude is about 4.0, and the comet should remain a naked-eye object until about the end of July.

A photograph of the comet taken at Juvisy on February 12 is reproduced in the April number of the *Bulletin de la Société astronomique de France*; at that time the tail showed as a feeble, fine trace about $1\frac{1}{2}^\circ$ long. Another photograph was taken on March 7 with nineteen minutes' exposure, but only a feeble image of the head was obtained. A drawing by M. Baldet, made on March 5, when the magnitude was estimated as 6.0, shows a V-shaped appendage, the angle between the two tails being 70° , and the southern tail being the faintest and shortest.

Reports from various countries emphasise the necessity for spreading sound knowledge concerning the comet. The suicide of a Hungarian farmer "on account of Halley's comet" is followed by a report from Odessa that in southern Russia there is a veritable popular terror, which is being exploited by unscrupulous persons for the purpose of obtaining money, for special prayers, &c., from the ignorant natives. We welcome, therefore, a brochure received from the Manila Weather Bureau, in which Father Zwack carefully analyses the alleged sources of catastrophe, and shows how utterly puerile they are. Such brochures, if printed in the vernacular, would do a great deal towards allaying excitement, which otherwise may lead to serious trouble.

COMET 1910a.—A number of observations of, and an ephemeris for, comet 1910a are published in No. 4400 of the *Astronomische Nachrichten*. Among the former are some, made near the end of January, by the late M. Charlois at the Nice Observatory, and an interesting set communicated by Dr. Ristenpart from the Santiago

Observatory. At Santiago they picked up the comet about three-quarters of an hour before noon on January 19 (23h. 15m., January 18), and followed it until after 6 p.m.; at the time of the first observation it was only 7° east and $3\frac{1}{2}^\circ$ north of the sun. Herr Castro, who made the position settings during the afternoon, noted a striking falling off in the apparent brightness of the comet during the $2\frac{1}{2}$ hours he had it under observation.

THE GALACTIC SYSTEM, ITS STRUCTURE AND ORIGIN.—An interesting discussion of the galactic system, its structure, origin, and relations in space, is published—in English—by Dr. Karl Bohlin in No. 10, vol. xliii., of the *Kungl. Svenska Vetenskapsakademiens Handlingar*. Having observed a large number of nebulae and clusters, and, in a previous paper, discussed the measures of the globular cluster M. 92, Dr. Bohlin was induced to take up the study of the distribution of the various classes of the heavenly bodies, and commenced with that of globular clusters. From this point of view he has studied the distribution of a large number of these objects, and concludes therefrom that their system is situated in the centre of the galactic system, for only on this assumption can their apparent clustering on one side of the galactic circle be explained. Extending the study to various other classes of celestial objects, the author evolves a systematic evolution of them which accounts for their apparent distribution and various forms. In this hypothesis planetary nebulae originally consist of rotating luminous shells filled with very tenuous matter. These shells, breaking down at their poles, form apparent "ring" nebulae with distinguishable nuclei. The galactic system is supposed to have been such a planetary nebula, having reached at present an advanced form of ring nebula, of which the system of globular clusters forms the nucleus; the spiral nebulae, clustered near the poles, parts of the broken shell; and the Milky Way, the equatorial belt. Diagrams illustrating these distributions, and twenty-seven reproductions from photographs of various nebulae, are shown on the six plates accompanying the paper.

SATURN'S SATELLITES AND RINGS.—In No. 610 of the revived *Astronomical Journal*, now edited by Prof. Lewis Boss, Prof. Barnard records some measures of the eclipses of Saturn's satellites, made by him during 1906-8. The measures are given in detail, and some interesting notes on the dimming of the satellites Rhea and Dione, immediately before the final disappearance, are appended. In the case of the former the loss of light amounted to as much as 2.0 to 2.5 magnitudes. Measures of the relative distances of the satellites and of the position-angles of the rings during the same period are also given.

THE SYSTEM OF ϵ HERCULIS.—From the investigation of a large number of plates taken at the Dominion Observatory, Ottawa, Mr. Harper has re-determined the orbit of the spectroscopic binary ϵ Herculis, and finds several departures from the elements determined from the 1907-8 spectrograms. The period, according to this later determination, is 4.0235 days, and is a varying quantity (the *Journal of the Royal Astronomical Society of Canada*, No. 5, vol. iii.).

THE GAZELLES OF SEISTAN.¹

MAJOR R. L. KENNION, British Consul at Seistan, has had the good fortune to bring to light what are practically two new species of gazelle from the Kain and Seistan districts of eastern Persia, specimens of both of these, presented by Major Kennion, being exhibited in the Natural History Museum. Of the first of these species, typified by the mounted head of a buck from Kain, two notices by myself appeared in the *Field* newspaper for 1908 (vol. cxi., pp. 70 and 499). In the earlier of these it was compared to the Atlas or edmi gazelle (*Gazella cuvieri*) and Merrill's gazelle (*G. merrilli*) of Palestine, with the former of which, and probably also with the latter, it agrees in the presence of horns in the female. Compared with the type-skull of Merrill's gazelle figured by Mr. O. Thomas in the Proceedings of the Zoological Society for 1904, vol.

¹ Communicated by permission of the Trustees of the British Museum.

ii., p. 348, the head of the Kain gazelle differs by its larger ($11\frac{1}{4}$ inches) and more fully ringed horns, the number of rings in this specimen being sixteen, and also by their less distinctly S-shaped curvature in profile, and rather more sublyrate form when seen from in front. In the general contour of the horns, the characters of the face-markings, the very tall ears, and the large bodily size, this gazelle comes, indeed, very close to the edmi, and in all these respects differs from the goitred gazelle (*G. subgutturosa*) of western Persia, as it also does by the smaller extent of the white area on the buttocks, which does not reach up to the root of the tail, but is restricted to the inner sides of the thighs. In this latter feature, shown in a mounted specimen, the Kain gazelle agrees with the Indian *G. bennetti*, from which it differs by its superior size (shoulder-height of a fully adult buck probably about 28 inches), larger ears, and more distinctly sublyrate and slightly incurving horns.

In the second notice I compared the Kain gazelle with the Yarkand gazelle (which I regard as specifically distinct from the goitred species), and named it *G. yarcandensis kennioni*, not being then aware that it differed by the presence of horns in the female and the smaller amount of white on the buttocks. The name *kennioni* would stand as a specific title were it not that in the Proceedings of the Zoological Society for 1873, p. 317, Dr. Blanford described a horned female gazelle from Jalk, on the Baluchi border of eastern Persia, as a new species under the name of *G. fuscifrons*. In a paper published in the same volume, p. 545, this species was recognised as valid by the late Sir Victor Brooke, who particularly referred to the large size of its ears as a distinctive feature, especially as compared to *subgutturosa*. Later on, however, Dr. Blanford, in the "Fauna of British India" (where Jalk is stated to be in Baluchistan, although in "Eastern Persia," he had rightly referred to it as forming the southern edge of the Seistan desert), identified *fuscifrons* with *bennetti*, on the ground that a male obtained by Sir O. St. John appeared inseparable from the latter. From the fact, however, that the Kain district, which is the northern continuation of the Seistan desert, is the home of a large gazelle allied to *bennetti* in the presence of horns in the female and the small extent of the white area on the rump, but with larger ears and rather more sublyrate horns, there can be no doubt that this gazelle is no other than *fuscifrons*, which must be re-established as a species. *Gazella yarcandensis kennioni* therefore becomes *G. fuscifrons*, although Kennion's gazelle may be retained as the English name.

This being so, it is doubtful whether the Indian *G. bennetti* really occurs in Persia at all. In "Eastern Persia" Dr. Blanford stated that he obtained a male referable to that species from the Bampur district of eastern Persia (alluded to as being in Baluchistan), which differed from Indian examples only in some details of the horns, adding that he believed this gazelle to extend on the lowlands to the head of the Persian Gulf, while above the 3000-foot contour it was replaced by the goitred gazelle, distinguishable, even at a distance, by its lighter colour. From the new evidence it appears that the lowland gazelle of the Persian Gulf is *fuscifrons* rather than *bennetti*.

The second of the Seistan gazelles is represented by an adult male standing about 39 inches at the shoulder, and characterised by the great size of the ears, the marked incurving of the tips of the sublyrate horns, and the small extent of the white area on the rump, which does not reach the root of the tail. In most of these features this species resembles the Yarkand gazelle, as it also does in the absence of horns in the female, although it differs by the small extent of the white on the rump, which in the Yarkand species (plate v. of Blanford's "Mammals of the Second Yarkand Mission") is very large and ascends high up on each side of the root of the tail. This gazelle greatly exceeds *subgutturosa* in size, as well as in the much larger ears, less divergent horns, and the smaller white rump-patch, but resembles that species in that the male has a "goitre." Taking the mounted specimen in the museum as the type, it may be known as the Seistan gazelle, *G. seistanica*.

The foregoing species collectively indicate a transition from the edmi and *bennetti* type on the one hand, to that of the goitred gazelle on the other, as is indicated in

the case of some of the Asiatic species by the following table:—

(a) Females horned; no goitre; tips of horns not distinctly inturned; rump-patch small.

(1) Indian gazelle—*G. bennetti*.

Height about 25 or 26 inches; ears moderate; no inturning of horn-tips.

(2) Kennion's gazelle—*G. fuscifrons*.

Larger, height probably about 28 inches; ears longer; horn-tips slightly inturned.

(a') Females (except *marica*) hornless; a goitre; tips of horns distinctly inturned.

(b) Rump-patch small; face-markings distinct.

(3) Seistan gazelle—*G. seistanica*.

Very large; height about 29 inches; ears very long; horns sublyrate.

(b') Rump-patch large.

(c) Face-markings; horns sublyrate; colour dark.

(4) Saikik, or Yarkand gazelle—*G. yarcandensis*.

About the size of last, but ears apparently shorter.

(c') Face-markings nearly obsolete; horns divergent; colour in winter very pale.

(5) Goitred gazelle—*G. subgutturosa*.

Size small, 24 to 26 inches; ears short; females hornless; dark lateral band faint.

(6) Marica gazelle—*G. marica*.

Ears taller; females horned; dark lateral band distinct.

The African edmi, and probably the Syrian Merrill's gazelle, come in the first group. The Mongolian *G. gutturosa* is a larger member of the last group, distinguished by the small size and peculiar form of the horns of the bucks, which do not diverge after the fashion of *subgutturosa*. The Central Asia *C. przewalskii* is another allied type.

Certain immature gazelles from Eastern Persia now exhibited in the Zoological Society's Gardens as *G. subgutturosa* are apparently *G. fuscifrons*.

R. LYDEKKER.

BOURNES, OR INTERMITTENT SPRINGS.

INTERMITTENT streams break out in our chalk valleys when there has been a partial return to the conditions of rainfall prevailing during the period of the excavation of the valleys. The effect of a heavy rainfall is not seen immediately. A bourne may, indeed, break out during a temporary drought following. Its immediate cause is the rise of the saturation-level until it intersects the bottom of the valley. The water then rises out of the ground, and flows until the curve of saturation sinks by reason of the relief afforded by the flow. While still rising, the bourne will make its appearance at successive points higher and higher up the valley.

These bournes afford a valuable clue to the method of formation of dry chalk valleys. Given a period of greater rainfall, and the permanent rise of the saturation-level would give a permanent stream, with considerable powers of excavation. Flints lining the bed of the Croydon Bournes are covered with a calcareous incrustation, so that solution and corrosion would both do work in the formation of the valley.

The earliest record of the Croydon and other bournes has been traced by Mr. Baldwin Latham to Warkworth's "Chronicle," which shows that in 1473 "womere watere ranne hugely." Bournes rose at St. Albans, Lewisham, and Canterbury, as well as at Croydon. In Leland's "Itinerary" reference is made to a bourne at Drelingore, near Dover, and this was also flowing in 1904, the year of the last great flow of the Croydon Bourne. In Yorkshire, the vipsies or gipseys are apparently similar to bournes. "Nailbourne" is a name formerly given to them in Kent, or, with a corruption of the spelling, "Eylebourn." "Wellesbourne" and "Winterbourne" are also met with. The Hertfordshire Bourne, which has again been active this year, was formerly known as the Wenmer, or Womer. This is referred to by Camden as breaking out near Watling Street. Childrey (1661) says that it is popularly believed that it never "breaketh out but it foretelleth dearth and scarcity of corn, or else some extraordinary dangerous times shortly to ensue." This, indeed, was a very customary superstition in connection with all these

bourne. Pestilence and plague followed them; but we can safely say that the share that they had in these results was to disturb the filth of previous years which had accumulated in their channels, and when they ran through undrained villages to scatter the germs of disease far and wide.

Croydon may be regarded as the centre of a number of bournes. In addition to that known as the Croydon Bourne, there is what was, no doubt, once its tributary bourne, the Merstham or Marlpit Lane Bourne. There was formerly one in the Wickham Valley, and others at Cheam, Carshalton, and Epsom. The Merstham Bourne, which is also flowing this year, yielded, according to Mr. Latham, 1,108,530 gallons a day on March 21 at Stoa's Nest. This now rises in a culvert which was made to receive the waters, when the springs ran high, in the building of Merstham Tunnel, and it follows the valley northward towards Croydon, but sinks into the ground, as it has from time immemorial, at Red Lion Green, Smitham Bottom. This disappearance has not yet been explained. If it continued a mile and a half further along the valley it would join the Croydon Bourne at Purley, and together they would proceed by the bourne culvert to swell the volume of the Wandle where it emerges from beneath Croydon.

The present flow of the Croydon Bourne is not so extensive as that of 1904, when its point of origin gradually receded from the grounds of the "Rose and Crown," Warlingham, and the gasworks, which became completely surrounded with water, to the Marden Valley, which it

surface of an iron or steel bar when permanently deformed, and they indicate the locality of the distortion. Observations show that these lines, in simple cases of loading, have an inclination of about 50° to the direction of maximum principal tension. Assuming that this inclination remains the same under more complex conditions of loading, it becomes possible to construct—at least in direction—the system of maximum principal tension from the lines of Lüders found upon a distorted piece. This method has been employed with some success, but it suffers from certain disadvantages. When the variation of stress is considerable, only those parts of the bar where the stress is greatest show any lines, unless the piece is so much deformed that the original distribution of stress is greatly altered. Thus the constructed stress system is either incomplete or inexact.

A more useful method is suggested by the similarity in the problems of elastic solids and of viscous fluids. Stress lines, which are lines of stress direction in a solid, possess certain points of similarity with stream lines, which are lines of flow direction in a liquid. In order to verify this connection, the comparison has been made between the stream system and the corresponding stress system for a number of two-dimensional cases.¹ The method employed consists in subjecting a steel bar of uniform thickness, but of varying width, to a tensile load, until a number of Lüders' lines are developed. The corresponding flow diagram is obtained, by means of the well-known Hele-Shaw apparatus, for a channel of the same outline as the bar. The position of one point on each line of Lüders is

Steel bars $2\frac{1}{2}$ inches wide, $\frac{1}{2}$ inch thick, reduced in width to $1\frac{1}{2}$ inches by means of (1) two saw cuts, (2) two angular notches of 90° , (3) two semicircular notches. The light bands are the lines of Lüders. The fine dark lines have been transferred from the corresponding flow diagrams (2), (4), and (6).

entered, as far as Bughill Farm. Thence the dry chalk valley winds away to the escarpment, and we may reasonably conclude that the stream formerly filled the whole valley. This year, although the gasworks at Whyteleafe have a fair amount of water in the field around them, the rising point has fallen short of Bughill Farm, and in the opposite direction has not reached Purley. Its yield was, however, reported by Mr. Latham as 2,300,980 gallons a day on March 21 at a spot below the "Rose and Crown." There is no regularity in the appearance of the bourne. It last was seen in the winter of 1903-4, and previously in 1897. There were annual flows from 1876 to 1883 inclusive, and it is interesting to note that Mr. Latham has accurately predicted the last fourteen flows from the rainfall measured in numerous stations on and about the Downs.

E. A. M.

STRESS LINES AND STREAM LINES.

THE general conditions of stress at any point in a loaded body have been reduced to certain mathematical equations, but there is considerable difficulty in applying these equations to any but the simplest cases. Experimental methods, therefore, are welcome, though they may give only approximations to correctness. One such method consists in deducing the stresses from the distortions produced by the load. The application of this method is frequently very difficult, but it has been simplified by the discovery and study of the phenomenon known as Lüders' lines.

Lüders' lines are markings which appear upon the

transferred to the flow diagram, and the form of a line of distortion passing through this point is constructed geometrically, assuming that the stream lines represent stress lines, and that the inclination of the lines of distortion to these is 50° . The constructed line is then superposed upon the corresponding line of Lüders; any divergence is an indication of a defective method or of faulty construction.

The figures illustrate the results of three such cases. Although the correspondence between the constructed lines and the actual lines of Lüders is not perfect, due chiefly to certain inherent defects in the method, there seems little doubt that in these cases the stream-line system is a fairly accurate representation of the system of maximum principal tension.

SCIENTIFIC KNOWLEDGE AND INDUSTRIAL DEVELOPMENT.

THE prizes and certificates of the successful students of the Bath Technical School were distributed by Principal E. H. Griffiths, F.R.S., of the University College, Cardiff, on February 2, when he delivered an address in which our educational system was discussed, and the value of technical education emphasised. We are indebted to the account of the proceedings in the *Bath Herald* of February 5, and to *Pen and Pencil* for November, 1909, for the facts contained in the following summary.

¹ "A New Experimental Method of Investigating Certain Systems of Stress." By G. H. Gulliver. Proceedings of the Royal Society of Edinburgh, Session 1909-10, vol. xxx., part i. (No. 3).

The latter periodical, which is issued by the students of the Cardiff Technical School, published a short article dealing with the value of science in industry by Principal Griffiths, which he elaborated in his address.

Principal Griffiths said that personally he prefers the words technical education rather than technical instruction, because we want in a technical school to do something more than the beginnings of a trade; we also want to expand the horizon, increase knowledge, and increase their abilities apart from the increased power it gives the students of earning their living later in life. We are, he continued, passing through a time in which there are certain difficulties naturally arising. There is no doubt that in the last ten years there has been a marked change in the aspect in which the question of education is regarded by the people, and those who need it. In such a time of change, as well as the advantages, there are dangers. We are spending an enormous sum of money—26,000,000.—from Imperial sources in educating children to read, write, learn arithmetic, and so on. Into the hands of these children weapons are being put, and then they are not taught how to use them. It is a fearful blot on the whole educational system of the country that we spend millions and millions of pounds in laying foundations, and do nothing further. A great portion of the money is wasted, and if it were not for the existence of technical schools and the continuation classes the situation would be worse still. The time must come, said Principal Griffiths, when, if the educational system of the country is to be used to the best advantage, it must be recognised that young people, on leaving primary schools, and not able to get the advantages of secondary education, must be compelled to give a certain portion of the time between the ages of sixteen, seventeen, and eighteen to studying something which may be of value to them in after life.

Dealing with technical education, he insisted that the prosperity of this country depends upon its industries, and that its industries are dependent on the application of science. The truth of the former statement, he said, will be generally admitted, but as regards the latter there is some scepticism. It is difficult, for example, to see the direct connection between the zoologist peering through his microscope and dissecting the minutest insects, and the progress of a great commercial undertaking. The connection is, however, close and real. Take, for example, that great work now in process of accomplishment, the Panama Canal. The man who successfully constructed the Suez Canal was defeated in Panama, not by the physical, or even the political, difficulties, but by malaria and yellow fever. It has been stated that in the enormous work which was done before the project was abandoned by the French, a human life was sacrificed for every cubic yard of earth excavated. This is now a story of the past, and the death-rate amongst the workers to-day but slightly exceeds that prevalent in many of the American States. How has this change come about? No small part has been played by the School of Tropical Medicine established by the University of Liverpool.

An elaborate and prolonged investigation, in the course of which valuable lives were unfortunately sacrificed, resulted in the discovery that the dissemination of both malaria and yellow fever is due to so insignificant a creature as a certain species of mosquito, a discovery which will undoubtedly have a profound effect, not only on such undertakings as the Panama Canal, but on the march of civilisation in the future.

It is interesting to reflect that this discovery, like many others which have profoundly affected the commercial community, has been made by men without any thought of financial return, but who have been prompted solely by their love of research and their desire to add to the common stock of knowledge of mankind. It is not too much to say that every increase in natural knowledge will ultimately prove to have its use and application in the affairs of daily life.

Faraday was the first to establish the fact that an electric current may be generated by the movement of a conductor in a magnetic field. When he first exhibited at the Royal Institution the crucial experiment which vindicated his reasoning in this matter, a lady afterwards inquired, "But if so, Prof. Faraday, what is the use of it?" His reply was a memorable one, "Madam, will you tell me

the use of a new-born child?" Reflect for a moment on the fruits of Faraday's discovery. True, numerous improvements have been made in the practical application of the principle by many workers, but all the applications of electricity which are now so frequent as to be regarded as familiar are based on the production of electricity by the expenditure of mechanical energy. Wherever a dynamo is used, there you have an application sprung from the brain of Faraday.

Mr. Stanley Jevons has made an approximate estimate of British capital invested in electrical undertakings which may be regarded as dependent on the mechanical generation of electrical power. It is safe to say that at least 185,000,000*l.* of capital are thus employed, and profitably employed, not only in increasing the comfort and welfare of the population as a whole, but in affording employment which otherwise would be wanting.

Examples of a similar kind could be multiplied almost indefinitely; but they are mentioned not so much to establish a proposition as to direct attention to the importance of scientific investigation, not only on its academic side, but also from a practical point of view.

It is by a recognition of this truth that Germany has in recent years outstripped us in some respects in the industrial race, and it is to such institutions as our technical schools and the laboratories of our colleges that we must look for the supply of men who are in the future to restore, if possible, the supremacy which seems to be passing from us. It must be remembered that not only must research receive encouragement, but we must train men in whom this country, as compared with both Germany and the United States, seems somewhat deficient—men who have sufficient scientific knowledge and ability to comprehend the discoveries of others and to apply such discoveries to the practical affairs of life. Men who can act as intermediaries between the laboratory and the market-place it is the special mission of our technical schools to supply.

In conclusion, Principal Griffiths commented on the fact that the man of business is not now as cynical of science as once he was, and, observing that no scientific discovery is useless, he added that there is nothing more likely to advance science than the institution of technical schools.

AËRONAUTICS.¹

ANY sensation of "wind" felt in a dirigible balloon is only that due to the independent speed of the balloon. It will always be the same, whether it be a following or a head wind, neither more nor less intense, because the surrounding wind is nothing but a movement of the atmosphere in which the balloon is submerged. Relatively to the ground below, a dirigible balloon may be going with the wind at 100 miles per hour, or against the wind making headway only at five miles an hour. If its engine be working at the same power in each case, the speed of the vessel relatively to the atmosphere is the same. Its envelope is only calculated to sustain the speed of which its engines are capable, and its stability depends upon a certain pressure of air not being exceeded. Bear in mind that wind is a body of calm air moving more or less rapidly. To the aeronaut wind does not exist. He is in calm: the earth is moving. A dirigible balloon may be in a current of air moving, say, from west to east at twenty miles per hour. With whatever speed it may be capable of, the balloon can move freely about in that current. The flow of air is always from the bows to the stern, and it is always of exactly the strength given by the independent speed of the airship.

No analogy of any marine vessel except the submarine is of any use to us; for in the ship you have either got a sail giving you leverage on the air, or you have the leverage of your keel or propeller giving you power against the wind. An airship cannot "tack" after the manner of a marine vessel. Nothing is to be gained by adopting a zig-zag course.

In mechanical flight the action of the air on the upper

¹ Abridged from Reports of Cantor Lectures delivered at the Royal Society of Arts by Mr. C. C. Turner and published in the *Journal of the Society*.

side of a plane has nothing whatever to do with lifting power. For instance, there is the familiar experiment with paper sometimes brought forward to show that the air passing over the back of the plane lifts it. As Phillips believed, it creates a vacuum on the upper rear extremity, and the paper naturally is pressed upwards; but let me explain the fallacy of the argument which seeks to show that the upper side of the plane therefore gives lifting power. If that piece of paper were free in the air, it would not matter how hard one blew on its upper surface it would not lift. It is only when it is held, in fact; and

FIG. 1.—Course of Airship against Side Wind. A, starting-point. B, destination. The shaded portion is a moving body of air, *i.e.* the wind. The diagonal line, C, is the path of the airship with regard to the air. The dotted horizontal line is its path with respect to the earth.

the lifting power is derived entirely from the expenditure of energy. The harder one blows the more it lifts. The power to rise is derived entirely from the energy with which one blows, or, in the alternative of a plane being driven through the air, entirely from the energy of the motor. There is no lift at all without the expenditure of power by the engine.

Scarcely any of these theories of the action of the air on the back of the plane have been mathematically formulated. Indeed, we are only on the threshold of the science.

No analogy of the behaviour of other fluids is of much use when we come to deal with the air. The air is not

FIG. 2.—In this case the wind is stronger, *i.e.* a longer body of air passes in the same time. The airship therefore has farther to travel with regard to its passage through the air and takes longer in order to arrive at B. Apparently, while the airship keeps to a much greater angle, it moves along the dotted line A. B.

a perfect fluid. It is a very turbulent fluid. There are vortices and reverse movements at the back of the plane. Practically nothing is known of the mathematics of the subject. The leading mathematicians are silent, and I have observed that the only theorists putting forward their conclusions as if they were capable of scientific proof are minor men of science. It is very necessary at present to keep an open mind. Sir George Greenhill and Mr. Horace Darwin, who have been appointed to the Aeronautical Advisory Committee, have not yet issued any statement as to their researches—not that they are unwilling, but prob-

ably because they are unable at present to speak with any certainty.

It seems a long way from cricket to flying, but a remark by Mr. P. F. Warner in an article on modern bowling the other day suggests an important consideration for aviators. The great cricketer was discussing "swerving" balls, and he said, "The heavier the air the greater the cushion, and in the thick, smoke-laden atmosphere of Sheffield or Bradford Hirst will swerve infinitely more than in the clearer and brighter climate of Sydney, Adelaide or Johannesburg." It is scarcely necessary that we should

point out the application to flight. An aëroplanist who found it easy to sustain flight at twenty miles an hour when near the ground might, on attaining an altitude of 4000 feet, find it necessary to increase his speed to forty miles an hour, or, rather, he could never get so high unless his engines were capable of giving the increased speed.

An attempt to secure some measure of stability is to place the planes at a dihedral angle, as in the Antoinette monoplane, in which the wings extend from the body in the form of a shallow V. This method was also formerly used by Blériot, but the tendency nowadays is to have horizontal and even slightly concave surfaces for the sake of the economy of surface involved. Now if Blériot reverted to the dihedral plane, he would have to make his machine two or three feet longer on each side. The dihedral plane is also wasteful of power. Instead, as we have seen, he relies entirely on the wing-warping arrangement for stability.

Cocking tried an inverted parachute in order to secure a steady fall instead of the swinging movement which all parachutists have to endure. It is true Cocking's apparatus gave way under the strain, but in any case it is quite certain that he did not give large enough diameter to his parachute, made on that principle, to sustain him.

This brings us to the discussion of a rather contentious point—that of the suspended centre of gravity. We have seen how early gliders depended below the sustaining planes. Now, in the Antoinette the weight is carried on

FIG. 3.—A Paper Experiment. The effect of blowing on the forward edge of a curved plane. Dotted lines show how paper rises.

the same level as the sustaining surface. Well, in the Blériot cross-Channel machine the centre of weight is slightly below the sustaining surface. In the Santos-Dumont it is considerably below. In the newest Blériot it is also well below, and in the Chauvière monoplane it is as much as 3 feet below. Now from what has been already said it will be seen that this secures stability only in the very smallest degree, and that the weight would have to be 30 or 40 feet below in order to secure the desired effect; and then you could never get the driving power necessary; but it is probable that M. Blériot, M. Santos-Dumont, and M. Chauvière, in constructing their machines in this way, have an eye, not to improve stability, but to other advantages. By this method they can obtain various constructional advantages, above all, a continuous leading edge by which they greatly economise lifting power. In short, they manage with a smaller machine. They make no effort, be it noted, to rely any less upon their wing-warping arrangements.

An aëroplane must travel at a certain speed to support itself at all. To enable it to rise to a higher altitude the power must be increased. There is, of course, a margin

of variability; but beyond this margin merely to point the elevating rudder at an increased angle is insufficient. You can obtain ascensional power at the expense of speed, but there is a point below which the speed must not be reduced.

There is, as we have seen, a natural speed for an *aéroplane*, and this natural speed is only elastic within limits. A remarkable variation on one machine was shown by M. Delagrangé at Doncaster. With a cross-Channel Blériot, to which he had attached a 50 horse-power Gnome motor, flying with the wind, he flew at a rate of forty

The near future will see machines in which three or four passengers can be carried, and in which the control can be in the hands of two pilots. Sooner or later we shall get the machine attempted with two motors instead of one; and quite certainly we shall have the machine with variable lifting surface and variable power.

We know that an *aéroplane* can descend safely on to water. M. Latham did that in his attempt to cross the Channel. Soon we shall have machines that can ascend from water.

The use of dirigible balloons, especially in this country, where strong breezes are common, calls for airship harbours at frequent intervals. Probably shelter walls capable of being turned round to the wind in any direction will be used. Each will have a staff of attendants, and the walls will not always be standing erect, but will be so made that they can be run up in a few minutes whenever an airship approaches and signals its need. To have them every ten miles or so all over the country always standing would be intolerable.

An airship has nothing to fear from any wind while she is in the air, but on landing even an ordinary breeze may wreck her. It is all very well for the Germans to show us what they can do with dirigible balloons, but in the great central plain of Europe there is comparatively little wind. They are not handicapped as we are; but in this country so frequently and quickly do strong winds spring up that it may be doubted whether any airships that could not be quickly deflated would be of use. We may discover that we can only employ the semi-rigid and the non-rigid balloon. The rigid balloon at Barrow may be a big blunder after all.

miles per hour. On the very next day, in a dead calm, with the same machine, he flew at the rate of fifty miles an hour. The difference, which was equivalent to 20 per cent., was due to the fact that he was getting more work out of the motor. On the same type of machine, with a 25 horse-power Anzani motor, the best speed was only about thirty-three miles per hour. M. Delagrangé said he could vary the speed 30 per cent. Another instance of driving a flying machine with increased power has been provided by M. Santos-Dumont, who put a 40 horse-power motor to his little monoplane, which gives about 300 per cent. more than the usual proportion of power to lifting area.

Now to obtain great variability of speed we shall have to have lifting surfaces that can be enlarged and diminished at will, and correspond with different engine-power.

The most scientific attempt to obtain the variable plane area is on the Chauvière monoplane, in which, while, in present designs, the leading edge remains rigid, the plane is quite flexible, and the rear edge can be let forward or pulled back by the tightening or slackening of cords; so that the width of the plane is either narrow or broad. When narrow, for high speed, the pressure of the air bulges the plane to an increased curve.

As to the development of the flying machine, differentiation will, in the main, respond to certain demands. We can clearly foresee development with both monoplane and biplane.

The racing *aéroplanes* will probably be monoplanes with comparatively small lifting surface, high speed giving the necessary lifting-power. The racing *aéroplane* will not carry a great weight, and the power of the engine will be required for driving at a great speed without more waste of energy than is unavoidable. It is, of course, an axiom that the greater the speed the less the waste of power. Monoplanes will very probably develop into a permanent racing type.

FIG. 4.—Position of Pilot. A, Antoinette, R.E.P. B, Blériot. C, Santos-Dumont.

FIG. 5.—The Chauvière Monoplane. An attempt to embody the principle of the variable lifting surface. The plane has a rigid leading edge, but is itself simply a sail. In flight the pressure of air underneath gives it a camber. The rear edge can be slackened and tightened at will to suit different speeds, the sides alternately or in unison.

A NATIONAL SYSTEM OF TECHNICAL EDUCATION.¹

THE problem of remedying the admitted inefficiency of our present methods of technical education, and of invigorating the industries of this country with progressive scientific spirit, while at the same time increasing the

¹ From a paper read before the Association of Teachers in Technical Institutions (West Yorkshire Branch) at Leeds, on April 2, by Dr. Robert Pohl.

supply of skilled workmen, is of the greatest national importance, and is a problem the solution of which, in view of international industrial competition, becomes daily more pressing. It is only natural, therefore, that expressions of discontent with the present conditions, and suggestions for improvement, should be heard from many sides; they come, not only from the educationists, but also from the employer, the representatives of the working classes, and the ratepayers, and with especial force from the social reformer; finally, we hear from Cabinet Ministers themselves that legislation on the subject is under consideration.

If we proceed to analyse the expressions of opinion, as revealed during the last twelve months in special papers, presidential addresses, reports and discussions, too numerous to refer to individually, there is a clear indication that, barely concealed under a superficial diversity of view-point, the ideas have already crystallised round two fundamental principles which are certain to form the basis of all future constructive work.

These are:—(1) There should be a thoroughly organised system of technical education, leading up from the primary and secondary schools to the technical school, and having, as its crown, the technical university, every stage of the system being in intimate contact with the next, so far as possible without overlapping, and the educational work must be carried out in the closest possible cooperation with the employer. (2) This system should be a national one; that is to say, the Board of Education should not only inspect and supervise the individual institutions, but should ensure proper coordination; extend by law the leaving age for children, when and where necessary; enlist by all available means the cooperation of employers, and introduce a uniform system of examinations and degrees; and it should, from its exalted position, watch the working of the system, comparing it with that of other nations, and generally employing and developing the powerful weapon of technical education in the interests of the industries and the progress of the nation as a whole.

I take it as being agreed upon that the scientific leaders of industry require much more complete training than the rank and file of the industrial army, chiefly the additional training of strict scientific accuracy, of research, and originality. That in view of the numbers to be dealt with in both sections, respectively, there must be a large number of schools for the rank and file in close contact with local industries, and a small number of colleges for the officers. This means decentralisation in the case of lower technical schools, and centralisation for the technical universities. I have dealt in a previous paper with the Prussian technical universities (*NATURE*, April 15, 1909, vol. lxxx., p. 205). How does Prussia attend to the needs of the rank and file? There were, in 1909, 23 national engineering schools, 24 national building schools, 7 national art and artisan schools, and 22 State-supported municipal technical schools of different kinds, including 6 textile schools and 7 higher textile schools. Most of these institutions do no evening work, and the students pass through systematic courses extending over several years. During this time they are not in contact with practice, except that the building students, making the best of climatic conditions, frequently work in summer and study during the winter months, and that other students sometimes do practical work during the summer vacations. Generally speaking, however, the students are not in contact with practice. I also incline to the view that there has been too much centralisation in this branch of technical education. As a consequence, there is a lack of intimate contact with local industries, and insufficient amalgamation of theory and practice. Furthermore, most of these schools do not really train skilled workmen and artisans, but what may be termed the non-commissioned officers of the industrial army. The courses are somewhat expensive, and, through the almost complete absence of a system of scholarships, they cater more for the middle classes than the working classes. Another defect, and a very serious one in my opinion, is the absence of systematic cooperation between these schools and the technical universities, whereby students of exceptional ability would be sent up to the latter.

In England the corresponding educational work is overwhelmingly carried on in evening classes, and, though in principle I am in the fullest agreement with those who object to all evening work and wish it transferred to the day, I cannot but admire the magnificent work now done under the course system in evening schools, and the most valuable and unique features of the same. What are they? It is, first and foremost, the intimate and continued contact of the students with practice which infuses their daily work with heightened interest derived from the application of their studies, and, on the other hand, reacts on the teacher and makes the courses, though they must remain theoretical, yet of a thoroughly practical nature and best suited to the needs of the local industries. It is, secondly, the complete elimination of the bitter disappointment which many day students, in proud possession of first-class certificates and diplomas, now experience when they find that they cannot secure any suitable employment. This "sandwich" or "half-time" system, which we so justly condemn when it is applied to primary education, is, in my view, the ideal system for the training of the industrial rank and file. I am therefore of opinion that those who desire to see the present evening work abolished, and the day schools developed on the German lines, are very ill-advised. Whatever we do, let us retain the great feature of the English principle, that is, the concurrent training in factory and school. Let us make the present evening courses much more efficient by establishing proper cooperation with the employers, and by reducing the hours of labour, so that it becomes possible gradually to shift the centre of gravity from the evening to the day. Thus we shall obtain all we are striving for without losing the great features I have emphasised, as well as the truly democratic spirit of the present system and its hold on the masses of the population. In advocating progress in this direction, we shall work in harmony with the enlightened employer and with the trades unions, and we have on our side the powerful influence of the social reformer as expressed in the reports of the Poor Law Commission. Indeed, the President of the Board of Education, in a reply to a deputation from the Trades Union Congress only a few days ago, indicated that legislation on these lines—including the raising of the leaving age and technical classes during daytime in cooperation with employers—is under consideration, and it remains to us to insist that the Bill shall be speedily produced and placed on the Statute book in a shape which conforms with our views.

We must convince employers that the developments which are shortly to take place are first and foremost in their own interests, and we should insist that definite provision be made in the promised Bill for an advisory board to be attached to each technical school, such board to have subcommittees representative of the chief local industries and trades; but there is a further, and, if possible, more important point to be considered. The technical school, as thus firmly established by law, must not be an isolated unit in our educational system, but it must be a link in a complete chain. It must join at the bottom with the secondary school, especially with the technical secondary laid down as a desideratum in our resolutions of last year, and it should lead up to the technical university above. It is the need for an organic connection of the ordinary work with the highest form of technical education on which I wish to lay particular stress. No better form can I imagine for this link than that of a comprehensive and national scheme of maintenance scholarships, by means of which the students of exceptional ability and enthusiasm are lifted up and trained to be the scientific leaders and original workers.

What would be the cost to the nation of such a scheme? Assuming 250 national scholarships to be awarded annually, tenable for four years, value 75*l.* per annum and free tuition, we arrive at the trifling expense for this highly productive scheme of 75,000*l.*, about one-thousandth part of what we spend every year on unproductive armaments. Surely, looking at it from a business point of view, no sounder investment could be imagined, and there is little doubt that if the nation would institute this magnificent

plan, the municipalities, the wealthy industrial and professional societies, and private benefactors, would come forward to expand it and make it more fruitful.

Thus we have arrived at the technical university, and in passing I will only remark that up to this level of technical education there is every likelihood of Prussia having shortly to learn a great deal from England. The aspect changes completely, however, when we contemplate the higher branches. In the latter, in Prussia we find thorough organisation and efficiency; in England we find chaos and waste of energy and money. The explanation is simple: the Prussian technical high schools are national institutions, just sufficient in number for the needs of the whole nation so as to allow of intense specialisation in all branches. The many English institutions attempting higher technical work were founded by private persons, guilds, societies, municipalities, and whosoever liked to distinguish himself in this direction. The national Government has made the sad mistake of generously supporting all these well-meant efforts, so far with little regard, apparently, to the effect of the one on the other. The borough, and even the county, is far too small a feeding area for a modern technical university, with its large staff of specialised experts in all branches, training original workers, carrying out industrial research, and generally permeating the industries with progressive ideas.

How will it be possible to bring about the formation of such efficient universities? Without doubt, the difficulties of this task are formidable, yet they can be surmounted by a strong Minister of Education, and the accomplishment will earn for him the gratitude of generations.

As an introduction to a discussion on this particular question, one or two suggestions may perhaps be acceptable. Needless to say, decisive steps in the direction indicated must be preceded by an exhaustive inquiry of a Royal Commission into the whole subject. One of the aims of the commission would be to discover a ready means of correlating the work of universities with that of other institutions which, as yet, is non-existent. It may be found desirable that all Exchequer grants for educational purposes, without exception, should pass through the Board of Education in such a manner that the grant becomes an effective weapon of organisation. Another important point to be settled is the number of technical universities needed, and their respective feeding areas. I believe that three for England and Wales, one for Scotland, and one for Ireland, or even less, would be found to be sufficient for many years to come. Finally, the most difficult point as to the method of procedure will have to be decided.

It appears not unlikely that, as a result of the inquiry of the special Royal Commission appointed last year, such amalgamation may soon be brought about so far as London is concerned, and an early extension of the principle to the provinces would then be within the range of probability. The leading institutions at present existing in each university area decided upon would form the constituent colleges; they might have the first and second years' courses in common, which, of necessity, would be generally scientific and educational in character, including such subjects as national economy, industrial history, industrial legislation, patent laws, &c., but the higher branches would be distributed according to the nature of the institutions and the industrial activities of the districts. Thus the desired concentration of effort and of students would be secured, and, by a process of natural development, the formation of a large staff of specialists in each branch working in intimate contact with their respective industries.

Higher technical education in England, if developed on such lines, would have adopted only one important point from the Prussian system, that is, organisation on a national basis, a point which, in my opinion, is indispensable to success. Other and less important points of similarity, such as the uniform system of examinations and of legally protected degrees, would come as a natural consequence. In more than one regard, of profound importance, however, the English would be far in advance of any existing system, so far as my knowledge goes;

first, in its democratic principle, culminating in the character of its students, who, gathered by a process of sifting and selection, represent the genius of the rising generation in whatever sphere it may have been born—a class, not of aristocratic idlers, but of enthusiastic workers. This ideal we shall approach only gradually, yet it is in sight, and we may accelerate its coming by advocating that the fees of the new universities for all except the scholarship students shall not be kept low, but shall be, at any rate, in proportion to the cost of such institutions. The scholarship students will thus predominate more and more, which makes it possible at the same time to adjust the number of highly trained men to the needs of the industries. We shall thus avoid excessive supply, which is a social and economic danger, and is a blame often, and not unjustly, attached to the German high schools; and, finally, the close cooperation of the new universities with the respective industries would be a unique feature. It would be maintained, not only, as in Germany, through the professors and lecturers, but through their advisory boards, and, what is perhaps most important, through the students themselves, who have been in contact with practice, not merely for a short term of pupillage like the average German student, but who have passed "through the mill."

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

DR. ARTHUR WILLEY, F.R.S., director of the natural history museum at Colombo, has been appointed to the chair of zoology at McGill University, Montreal.

ON Friday, April 22, the Education Bill restricting half-time employment will be considered by the House of Commons if the Government leave the day free. It is hoped that time will be found for the consideration of this important and long-delayed reform in the present Parliament.

THE London Inter-collegiate Scholarships Board announces that an examination will be held on May 10 for twenty entrance scholarships and exhibitions of an aggregate total value of about 1500l.; open to men and women, and tenable in the faculties of arts, science, and engineering of University College, King's College, and the East London College. Candidates must have passed the matriculation examination of the University of London, or an examination accepted in lieu thereof, or be able to furnish some evidence of having had a sound general education. Full particulars and entry forms may be obtained from the secretary of the Board, Mr. Alfred E. G. Attoe, University College, Gower Street, London, W.C.

THE Department of Agriculture and Technical Instruction for Ireland will in August next award not more than six industrial scholarships to persons engaged in industries, such as the woollen, linen, leather, and tanning industries. The object of these scholarships is to enable selected persons, who must already have been engaged in one of the higher branches of the industry, to take a full course of instruction in an institution providing special courses of an approved character, with the view of training them for the management of such an industry. The scholarships will be tenable at some higher institution, to be approved by the Department, in which the industry, and the principles underlying it, are taught. They will be of the value of 80l. each, and may be renewed for a second or a third year at the discretion of the Department. The Department will also award not more than six commercial scholarships to young men having a sound general education and some commercial experience. The object is to afford facilities for the holders to obtain training in some higher institution, approved by the Department, with the view of their employment as teachers of commercial subjects in Ireland. The commercial scholarships are of the value of 100l. each, and are tenable for two years.

On the occasion of the opening of the Carnegie Science Building at Acadia University, Wolfville, N.S., last October, Prof. H. A. Bumstead, of Yale University, delivered an address on the functions of a university laboratory. A reprint of the address is published in *Science* of March 11. After dealing with scientific studies from the disciplinary and ethical points of view, and urging that they are peculiarly adapted to the purpose of leading young men into the paths of careful, sensible, fearless, original thinking, he pointed out that laboratories have a much higher educational function to perform than merely to produce engineers or technical chemists or practising physicians; but Prof. Bumstead insisted most on the laboratory being a place for research. True research, real scientific pioneering, does not strongly appeal to the general public; its applications may be remote, it shows no immediate profit, its achievements are not spectacular, and are often too technical to be understood fully by any but experts. Thus it comes about that it must be encouraged and supported by the more enlightened fraction of mankind, and the chief agency through which this support may be given is the university or college. No other institution has been devised or seems likely to be invented which can perform the task so well. Research is not altogether a business, but an art as well, and that while organisation and division of labour may be the life of business, it is not the soul of art. To produce the highest results in scientific research there must be individuality and freedom, and there is room for far more individuality in a university laboratory than in any special research laboratory which has hitherto been established. Engaging in research is the best way and the only certain way for a teacher to keep himself alive intellectually and to retain his spirit and enthusiasm to the end. Even if the college he serves regards teaching and not research as its chief business, even then a professor must be given a reasonable amount of time and reasonable opportunities for research in order that he may keep his intellectual health, just as he is given time for physical exercise in order that he may maintain his bodily health.

WHEN we directed attention about two years ago to the second part of the first volume of the *Journal of the Municipal School of Technology*, Manchester, a volume of 130 pages of reprints of papers written by members of the staff of the school during the years 1903-7, we expressed doubt as to whether the output of research from the school was adequate in view of the fact that the staff numbered 100. The appearance of vol. ii. of the journal, which contains nearly 300 pages, and covers the papers published by the staff during the year 1908 only, removes all possibility of doubt on this score, and shows conclusively that the educational authorities of Manchester are alive to the importance of creating an atmosphere of investigation throughout the school. Of the sixteen papers reprinted in the second volume, three deal with pure chemistry, and form part of the series on the relations between outer form and chemical structure with which Prof. Pope's name is so closely associated; six deal with cotton, the staple trade of Manchester; five deal with electrical engineering and its teaching; one with mechanical and one with sanitary engineering. This list shows that the most important departments are all permeated by the desire to advance the subject with which they deal, and we may hope for a long succession of volumes from the school like the one before us. In the note referred to above regret was expressed that there seemed to be little evidence that the larger polytechnics in and about London, and the technical schools in the great towns of the provinces, e.g. Birmingham, Glasgow, and Belfast, adequately appreciated the importance of making themselves, above everything, centres of research for the solution of those problems which the highly specialised processes carried out in each district are constantly encountering. Far too many of the institutions of this type distributed over the country are content to record the thousands who have been taught elementary science within their walls, when the record is but one of their failure to do anything more than fill in some of the most conspicuous gaps in the education of those who come to them from the primary or secondary schools of the district. It is necessary to urge

such schools to leave elementary-school work to the elementary schools, and to make themselves efficient as centres for the higher work of teaching and research in the subjects which bear on the principal trades of the district. May the example of Manchester spur them on to a better use of their opportunities.

SOCIETIES AND ACADEMIES.

LONDON.

Zoological Society, April 5.—Prof. E. A. Minchin, vice-president, in the chair.—R. H. **Whitehouse**: The caudal fin of the Teleostomi. The paper dealt with the structure of the caudal fin in about fifty different species of fishes, mostly Teleostei, and representative of nearly all the sub-groups. After each sub-group a few general remarks were added, and these were followed by a short summary of results dealing with definitions and the taxonomic value of the caudal fin.—T. M. S. **English**: Some notes on Tasmanian frogs. The paper was based on observations made during rather more than two years' residence in Tasmania.

PARIS.

Academy of Sciences, April 4.—M. Émile Picard in the chair.—The president announced the death of A. Agassiz, foreign associate.—Wilfred **de Fonvielle**: The theory of Fontenelle relating to the constitution of comets. The author maintains the possibility of Fontenelle's view that the comet acts as a gaseous lens, and discusses Kepler's objections to this theory.—J. **Haag**: The spherical representation of certain families of Lamé.—René **Arnoux**: The longitudinal equilibrium and curvature of the carrying surfaces of aeroplanes. The effect of increasing the curvature of the supporting surfaces is to increase the power of support, but, at the same time, the resistance to translation is increased, and the longitudinal equilibrium becomes unstable.—A. **Votton** and H. **Mouton**: Havelock's relation between double refraction and the index of refraction. Havelock's formula has been verified experimentally by Skinner and McComb for the magnetic double refraction of eight liquids, and the authors have also verified it for nitrobenzene. This formula is based on the assumption that the field modifies the distribution, but it is also consistent with the hypothesis that there is an orientation of the anisotropic molecules.—F. **Croze**: The prolongation of the band spectrum of nitrogen in the extreme red and the infra-red.—V. **Crémieu**: A systematic error limiting the precision of the Cavendish experiment. A new method for the study of gravitation. The error is caused by a supplementary couple resulting from the bending of the supporting wire. A method is outlined by which this error can be eliminated.—C. **Chéneveau**: The specific refractive powers or optical constants of dissolved substances in very dilute solution. An interference method was used, and the error due to differences of temperature in the two vessels discovered and eliminated. Ionisation does not appear to have any sensible influence on the refractive power of a dissolved substance in solutions of which the concentrations are more than 0.5 gram per litre.—Louis **Wortenstein**: The paths of radio-active projections.—A. **Besson** and L. **Fournier**: The reduction of the chlorides of boron and arsenic by hydrogen under the influence of the silent discharge. Arsenic trichloride is reduced, and a substance is formed the composition of which corresponds to $As_{11}Cl$; this may possibly be a mixture of arsenic and a lower chloride than $AsCl_3$. No subchloride of boron could be obtained.—J. **Bougault**: The acid-alcohols of conifers. Juniperic and sabinic acids. Juniperic acid was proved to be $CH_2(OH).(CH_2)_{14}.CO_2H$, and sabinic acid

Thapsic acid, extracted by F. Canzoneri from the resin of *Thapsia Garganica*, was shown to be identical with juniperic acid.—Marcel **Délépine**: Some organic compounds spontaneously oxidisable with phosphorescence. Eleven substances are described which possess this property, all having in common the group $(S=C-O-)$.—E. **Voisenot**: The detection of hexamethylenetetramine

in musts and wines. The process is based on the fractional distillation of the acidified wine, followed by a colour test with albumen, hydrochloric acid, and nitrous acid. The latter is stated to be a specific test for formaldehyde.—**P. Vuillemin**: Materials for a rational classification of the *Fungi imperfecti*.—**M. Biéler-Chatelan**: A drainage effect.—**H. Bordier** and **R. Horand**: The action of the ultra-violet rays on trypanosomes. The action of the rays has been followed continuously under the microscope. The trypanosomes become rapidly granular, and their bodies, having the same refractive index as the surrounding medium, cannot be seen.—**M. Lecoq**: The toxic power of metalloidal arsenic. This is much less than that of corresponding quantities of arsenious oxide.—**Emm. Pozzi-Escot**: A bird of the runner family, confined to the high summits of the Peruvian Andes.—**Charles Nicolle** and **L. Manceaux**: The experimental reproduction of the pustule of the East in the dog. The possibly canine origin of this disease.—**F. Diénert**: The search for fluorescent substances in mineral waters.

DIARY OF SOCIETIES.

THURSDAY, APRIL 14.

ROYAL SOCIETY, at 4.30.—On the Viscous Flow in Metals and Allied Phenomena: **E. N. da C. Andrade**.—The Refraction and Dispersion of Argon, and Redeterminations of the Dispersion of Helium, Neon, Krypton and Xenon: **C. and M. Cuthbertson**.—The Action of the Radiation from Radium Bromide upon the Skin of the Ear of the Rabbit: **J. O. W. Barratt**.—A Physiological Effect of an Alternating Magnetic Field: **Prof. S. P. Thompson, F.R.S.**

ROYAL INSTITUTION, at 3.—The Himalayan Region: **Dr. Tom G. Longstaff**.

THE CORRESPONDENCE OF OLBERS AND GAUSS.

Wilhelm Olbers, sein Leben und seine Werke. Im Auftrage der Nachkommen herausgegeben von Dr. C. Schilling. Zweiter Band, Briefwechsel zwischen Olbers und Gauss. Zweite Abtheilung. Pp. vi+758. (Berlin: J. Springer, 1909.) Price 16 marks.

TEN years have elapsed since the first part of this volume appeared (*NATURE*, vol. lxi., p. 486), the editor having been prevented by other occupations from completing his work, until he secured the co-operation of Dr. Kramer. The present part (or rather volume) comprises the years from 1820 to the death of Olbers in 1840. Although it forms part of a publication intended to keep alive the memory of Olbers, the real hero of this volume is Gauss, not only because he was a greater man than his correspondent, but also because the scientific work of Olbers was almost finished before 1820. All the same, the volume serves to complete the picture of the charming personality of Olbers with which previously published letters had supplied us, while it almost forms a diary of the scientific work of Gauss during the years 1820-40.

At the beginning of 1820 the new transit circle by Reichenbach had just been mounted at the Göttingen Observatory, and Gauss was busy studying what was practically a new form of instrument. Though he was very fond of observing, the Göttingen Observatory did not accomplish as much as might have been expected, considering the devotion of the director to astronomy and the fine instruments at his disposal. This was partly caused by the various other pieces of work in practical science which occupied so much of his time, partly by his never having an assistant until the death of Harding (in 1834), who held a rather anomalous position. Geodetic work soon came to occupy most of Gauss's time. The continuation of the Danish survey southward through Hanover was finally decided on in 1820, and the work in the field was carried out during the summers of the next five years, most of it by Gauss himself, who, both on this and on the computation of the results, spent a vast amount of time. One cannot help regretting that so great a mathematician should have been obliged or found it necessary to do so much routine work himself instead of merely supervising its execution by others. No doubt this work gave rise to several theoretical investigations of great value, and occasioned the invention of the heliograph by Gauss, but these results would have been produced equally well by his brain if the fatiguing work in the field and the arithmetical drudgery at home had been done for him. Attempts were repeatedly made at Berlin, especially in 1824, to get a post created for Gauss in connection with the Academy of Sciences, but they were never successful. At Berlin he would have been relieved of all teaching work, which he greatly disliked, and his time would have been almost altogether his own. The work on the survey continued to drag

on; the present volume gives full details about the various stages of it, but everything of permanent interest has already been given in excerpts from these letters in Gauss's collected works.

During the second half of the period in question Gauss devoted himself chiefly to researches on terrestrial magnetism, and continued to keep Olbers posted on the progress of this work. Naturally the electromagnetic telegraph which was established in 1833 between the observatory, the Johannisthurm, and the physical laboratory, a distance of several thousand yards, is described with pride and in full anticipation of the great possibilities of the invention. The cooperation of Gauss and Weber in the magnetic work came to an end in 1837, when Weber, as one of the seven professors who had protested against the King's violation of the constitution, had to leave Göttingen. In his letters, Gauss expresses himself with great caution about this unpleasant affair, because, as he says himself, it was not at all unlikely that letters were tampered with while they were on the way.

Though Olbers in his letters had no great investigations to describe to his friend, he had always something of interest to say about the current scientific events of the day. It is interesting to see him occasionally give his opinion about some of his contemporaries. Thus he considered W. Herschel "a good mathematical head, but too much wanting as regards scientific education, though his, so to say, natural mathematics generally guided him in the right direction." As to Schröter, Olbers thought that though Mädler had spoken rather too severely of him, he certainly had very exaggerated ideas as to what his telescopes could show, and believed that no one but Herschel could verify what he himself saw or imagined he saw.

As a sort of running commentary on the progress of astronomy, Olbers's letters are of great interest, but their value to most readers would have been much increased if the editors had been more liberal with footnotes giving references to astronomical literature. Thus, when Gauss sets forth his grave doubts as to the alleged fraud of d'Angos, it should have been stated that Gauss much later wrote a short paper on this subject, which was printed after his death; also that the researches of d'Arrest and Gylden have rendered it at least extremely doubtful whether any fraud had been committed. Similarly, when Olbers assumes it to have been proved that Hell falsified his observations of the transit of Venus, it should have been pointed out that Newcomb most thoroughly established Hell's innocence. The nebula mentioned on p. 43 is N.G.C. 7293, and the mysterious nebula of Cacciatore (p. 461) is N.G.C. 6341, as to which J. Herschel showed long ago that Cacciatore had simply made a blunder in identifying a star (*Gen. Cat.*, p. 37).

This correspondence fills two stout volumes in large octavo, 1500 pages in all. Is it really worth while to print every single word that a great man puts on paper? It is natural that a man should tell his intimate friend at some length that his wife and children have measles, or repeatedly give vent to his sorrow and indignation at the conduct of a good-for-nothing

son; but it goes without saying that he does not want all this printed. A judicious selection from these 734 letters would have been very much more valuable than this unsifted mass of important and unimportant matter. There is an excellent index, which will be of great use to a reader desirous of referring to any particular subject. In an appendix are given some letters about the negotiations to get Gauss an appointment at Berlin, and three very interesting letters from Bessel to Olbers from the year 1812, which have only recently been found.

J. L. E. D.

COLONIAL FRUIT-GROWING.

Fruit-ranching in British Columbia. By J. T. Bealby. Pp. viii + 196. (London: A. and C. Black, 1909.) Price 3s. 6d. net.

THIS is a practical work on the subject of fruit-growing in British Columbia, and we recommend it to any who have the intention of emigrating for the purpose of engaging in this healthful and interesting pursuit. But not to these alone, for the style in which it is written is sufficiently good to make the reading agreeable to the general public. It sets forth in plain but picturesque language the reasons that led the rancher to select British Columbia for the scene of his operations; it describes his journey out, relates the difficulties the new settler had to overcome, and proceeds to describe the measure of success that soon attended his labours.

This success enabled him, not only to win prizes for fruit at exhibitions in British Columbia and in the United States, but also to send excellent apples to the Royal Horticultural Society's shows in London, and gain for them the Society's gold medal!

The figures relating to the crops obtainable per acre in British Columbia are almost bewildering to the cultivator in this country, who can never be certain, even of a moderate return, until the danger of spring frosts is past at the end of May. The difference is explained by the sunnier skies, freedom from violent winds and storms, and the presence of a most fertile soil. The allurements these things offer are only to those who are content to undertake the hard work inseparable from colonisation. Unless the "tenderfoot" possesses a sufficient capital to enable him to purchase an estate already planted, he must commence by clearing away the trees and under-shrub from his plot, and in this and all other work he must improvise ways and means for carrying out the details which are simple enough in a more thickly populated country, but very difficult in parts of a colony in the first stages of development.

In these matters the reader will find much interesting information in Mr. Bealby's work. He will realise how important it is that the work of preparing the ground shall be done in a thorough manner, and that careful consideration shall be given to the planting of suitable trees. The settler has to take into account the kinds of fruit most likely to yield profitable returns, and having decided thus far he must select the best varieties of each kind. He must study his market, the means that exist for sending the fruits to market, and the length of time they will be on transit.

The advice given on such matters as these is perfectly sound, and therefore calculated to assist settlers very materially, provided that instead of slavishly following them in detail they wisely modify them to suit best their own circumstances.

Mr. Bealby probably underestimates the cost of preparing the land, but this may be expected to vary in different districts, and he appears to place too much importance upon the fact that in the Kootenay and Okanagan districts the fruit plantations are more free from insect and fungal pests than in other localities. The explanation of this comparative immunity will probably be found in the newness of the land. Pests are seldom epidemic unless the host-plants are present in large numbers and so facilitate the spread of insects or fungi, but they usually appear when the cultivator has planted vast areas with the same kind of tree, or crowded them into a hot-house, as is the case with tomato and cucumber culture in our own country.

For this same reason, the best preventive is to plant thinly, allowing each tree as much isolation as can be spared with due regard to the yield per acre. It is satisfactory from this point of view to note that, so far as can be seen from the excellent illustrations contained in the book, it is not the practice to crowd the trees together in British Columbia. The trees depicted appear to have plenty of space around them, therefore they are exposed well on all their sides to the good influences of sunshine and air, which are conducive to healthy growth and a free cropping habit.

The evidence the book contains of the enormous help the settler in British Columbia may expect to receive from the Department of Agriculture and the British Columbia Fruit-Growers' Association should be an extra inducement to emigrants to select this country for their new home. We hope Mr. Bealby will return to the subject when he has gained further experience, for it has to be noted that he has only been engaged in the industry since 1907, a fact that may cause some to receive his recommendations with a certain amount of reserve, especially so far as they relate to yields, prices, and returns.

STEAM TABLES.

Tables and Diagrams of the Thermal Properties of Saturated and Superheated Steam. By L. S. Marks and H. N. Davis. Pp. 106. (London: Longmans, Green and Co., 1909.) Price 7s. 6d. net.

AN immense amount of painstaking work is represented by this little volume, which will, we think, be of undoubted use to all physicists and engineers who have to deal with problems involving the influence of heat upon water and steam. The two authors are connected respectively with the engineering and physical sides of the great American University of Harvard, and they have evidently formed a combination well suited for such an investigation as this. Until quite recently the only authoritative experiments over a considerable range of steam pressures and temperatures were those made by Regnault more than sixty years ago. We now have, however, the results of later experiments by Dieterici, Smith, Griffiths, Henning, Joly, Grindley, Peake,

Griessmann, Knoblauch, Thomas, and others. As the result of a careful weighing of these various experiments, the authors present the following formula connecting the total heat of one pound of dry saturated steam with its temperature (Fahrenheit):—

$$H = 1150.3 + 0.7745(t - 212) - 0.000550(t - 212)^2.$$

The equation heretofore in use was $H = 1082 + 0.305t$, which may also be put in the more directly comparable form of

$$H = 1147 + 0.305(t - 212).$$

It will be seen that there is a considerable difference in form between these two statements, although as one is of the second degree and the other of the first it is not easy to tell at sight by how much they would differ over the working range. The best way of comparing them is to set the figures in the old steam tables side by side with those in the new. This we have done for each increase of 50 lb. in the pressure. The figures in brackets are those of the old tables, as taken from such a standard book as Perry's "Steam Engine," and the remaining figures are those of the tables now published.

Pressure lb./in. ²	Tempera- ture ° F.	Sp. Vol. Cu. Ft. per lb.	Latent Heat	Total Heat	Entropy of Steam
I	101.83 (102)	333.0 (334.2)	1034.6 (1043)	1104.4 (1113.0)	1.9754 (1.987)
50	281.0 (280.8)	8.51 (8.34)	923.5 (916.6)	1173.6 (1167.6)	1.6581 (1.649)
100	327.8 (327.6)	4.429 (4.356)	888.0 (882.9)	1186.3 (1181.8)	1.6020 (1.596)
150	358.5 (358.2)	3.012 (2.978)	863.2 (860.6)	1193.4 (1191.2)	1.5692 (1.566)
200	381.9 (381.6)	2.290 (2.273)	843.2 (843.4)	1198.1 (1198.3)	1.5456 (1.545)
250	401.1 (401)	1.850 (1.84)	826.3 (—)	1201.5 (1204)	1.5276 (1.520)
300	417.5 (417.5)	1.551 (1.55)	811.3 (—)	1204.1 (1208.9)	1.5129 (1.515)

It will be seen that at the ordinary steam-engine pressures of 150 to 250 lb./in.², there is very little difference between the two sets of figures, but that at lower pressures there is some variation, although in no case is it extreme. On the other hand, many calculations involve the estimation of differences of heat content, and in those cases it is essential to allow for any such corrections in the received steam tables. It is, therefore, hardly too much, perhaps, to suggest to those who have made important calculations with the old tables that they should recalculate their results on the basis of these later figures.

Anyone reading carefully what the authors are able to say in support of the figures they give must concede that their researches have produced tables based on what is probably the most accurate data procurable at the present time. The theory of the steam engine will be considerably aided thereby, and one cannot but regret that there are no tables of equal accuracy applicable to the working fluid in the internal-combustion engine.

We regret that the authors should have presented the bulk of their results in the unscientific Fahrenheit scale. All who know the pitfalls which beset the paths of students will agree that, of them all, the most common and dangerous is the elusive

"32" in the Fahrenheit scale. To have such a constant is never of any use, and its avoidance is the great merit of the centigrade scale. We should like to see these tables published throughout in the scientific temperature scale.

The book contains two sheets of very useful curves, which enable large numbers of simple problems to be solved by mere inspection. Among the illustrations given we quote the following:—

(a) A vessel of 4 cu. ft. capacity contains 0.2 lb. of water and 0.8 lb. steam. What is the pressure?

(b) What is the entropy of 1 lb. of steam at 100 lb. pressure and 450° F.?

(c) Steam of 140 lb. pressure, superheated 120° F., expands adiabatically with a ratio of expansion of 6. What are the pressure and quality at the end of expansion?

(d) Steam at 100 lb. pressure, superheated 60° F., expands in a nozzle to a pressure of 2 lb./in.². What is its final velocity?

(e) Steam in a throttling calorimeter with a pressure of 17 lb./in.², and a temperature of 265° F. The initial pressure of the steam was 100 lb./in.². What was its initial quality?

It will be admitted that the ready facility with which such problems can be solved by two simple sheets of curves is a great gain, and many workers in science and engineering will be thankful for this help.

H. E. WIMPERIS.

SNAKE VENOMS.

SNAKE VENOMS. An Investigation of Venomous Snakes, with Special Reference to the Phenomena of their Venoms. By Dr. Hideyo Noguchi. Pp. xvii+315. (Washington: Carnegie Institution of Washington, 1909.)

IT is now forty years since Fayrer and Weir Mitchell laid the experimental foundations of knowledge of the chemical characters and physiological actions of snake venoms, their investigations being inspired largely by the desire to combat the high annual death rate from snake-bite. The study of snake venoms has, however, obtained a greater interest since the publication, about fifteen years ago, of observations demonstrating the possibility of producing a high degree of immunity in animals and proving the antidotal properties of the serum of the immunised animals. These phenomena in regard to snake venoms, having been brought into line with similar phenomena in regard to bacterial toxins especially, have been bound up with, and have contributed largely to, the elucidation of the problems of immunity which have in so many directions influenced modern medical thought. Hence there has arisen in regard to snake venoms a literature of high importance, and, from its involving scientific investigators in many countries, a literature necessarily extensive and dispersed.

As the author of this book states, there is at this time, in the English language, no single work which treats of the zoological, anatomical, physiological, and pathological characteristics of venomous snakes with special reference to the properties of their venoms. As something more than a mere summary of the position

of the present knowledge concerning snake venoms, Noguchi's publication merits high praise, and it possesses in addition a vitality which can belong to such a work only when its author has taken a living part in the researches by which this knowledge has been acquired.

It is impossible here to do more than indicate the scope of the book. The earlier sections deal especially with the morphology and geographical distribution of venomous snakes, and with the description of their poison apparatus. The toxic secretions, their physical and chemical properties, and the effects of various physical and chemical agents upon them are then discussed. A summary is given of the symptoms produced by snake-bite in man and by experimental poisoning in animals, and the intimate nature of these effects on the different systems is then taken up in detail. The last sections deal with the problems of immunity to venoms—artificial immunisation, the specificity and therapeutic value of antivenins, the interaction between venom and antivenin, natural immunity, and the treatment of snake-bite.

It may be pointed out that the logical sequence of the last chapters is marred by the somewhat irrelevant interpolation of sections on the effects of venom on cold-blooded animals, plants, &c., between the chapter on natural immunity and that on the treatment of snake-bite. We believe improvement would be obtained by considerable rearrangement of the order of the sections.

The book contains many excellent illustrations, especially of the different species of venomous snakes, their anatomical features, and the pathological changes induced in the tissues by venoms. Several of the illustrations are reproduced from Fayrer's classic work, but many are original. For a book so well illustrated, the binding, in the form we have seen it, is inadequate.

As being the most important practical outcome of the researches epitomised in this publication, the problems concerned with the treatment of snake-bite call for special mention. In regard to the nature of antidotism, Noguchi definitely adopts the view, first propounded, and supported by convincing proof, by Fraser, that this antidotism is not of the nature of a vital action, but of a chemical reaction, between the antivenin and the venom. This view has subsequently been adopted by Calmette, who at first insisted on its being a vital process, and also by Ehrlich in relation to the closely allied antidotism of pathogenic toxins by antitoxins. In its relation to venoms it has also received further support from experiments by Martin and Cherry, and by Stephens and Myers, respectively summarised in pp. 248 and 140 of Noguchi's book.

With respect to treatment, the author chiefly favours specific treatment by antivenins, and expresses the hope and expectation that sufficiently powerful antivenins may yet be produced to cure more severe cases of snake-bite than can yet be done. He emphasises the necessity, as Fraser had experimentally demonstrated, of using large quantities of antivenin, a general principle now being extended to the therapeutic use of antitoxins in disease. He places in a subordinate position all non-specific agents, such as permanganate of potash or chloride of gold, the anti-

dotal effects of which he believes to be very restricted, but still of some value as being quickly and conveniently applicable.

We may further mention that the book contains a good workable bibliography. It is a book which will be of great service to future investigators.

THE EVOLUTION OF MAN'S STRUCTURE.

History of the Human Body. By Prof. H. H. Wilder. Pp. xii+573. (New York: Henry Holt and Company, 1909.) Price 3 dollars.

PROF. WILDER defines the twofold purpose of his book, as, "*first*, to present the results of modern anatomical and embryological research relative to the human structure in a form accessible to the general student, and, *secondly*, to furnish students of technical human anatomy with a basis upon which to rest their knowledge of details;" and there can be no doubt that, as the founder of a village newspaper would express it, he has "supplied a long felt want."

So much technical knowledge has to be acquired by the modern medical student in the brief span of time between matriculation and graduation that there is an ever-insistent tendency to curtail the preliminary scientific subjects in the medical curriculum. The effects of a scamped education in biology are becoming more manifest every year in the writings of anatomists and physiologists, when, as so often happens, the results of long and arduous researches are thrown away for the lack of a modicum of zoological or morphological knowledge.

Prof. Wilder's book, if placed in the hands of the medical student, will help him to bridge the gap between his biological and anatomical studies, and, in the later stages of his career, will help to save him from solecisms such as are being perpetrated far too frequently at the present time.

The wide scope of the work is indicated by the titles of its chapters, which deal with "the continuity of life," "the phylogenesis of vertebrates," "the ontogenesis of vertebrates," the integumentary, skeletal, muscular, digestive (and respiratory), vascular, urogenital, and nervous systems, the sense-organs, and "the ancestry of vertebrates," and an appendix on the classification of vertebrates.

The first chapter explains the fundamental principles implied in the terms phylogenesis and ontogenesis, which form the subjects of the second and third chapters respectively.

The account given in these three chapters (a) of the factors which played some part in the evolution of man, and (b) of the line of man's ancestry, is lucid, and, on the whole, satisfactory. The author has entirely failed, however, to realise and to set forth the immense importance which must be assigned to the Dipnoi in supplying evidence for explaining the evolution of the Amniota.

In chapters iii. to xi. (inclusive) the author has clearly stated the facts of comparative anatomy which throw light upon the morphology of the various systems of the human body, which I have already enumerated. These portions of the work are of considerable value, not only to the student of human

anatomy who wants to learn how the organs of man's body have come to assume their form and structure, but also to the zoologist, who will find in this book a concise statement of the light thrown upon the structure of vertebrates in general by the detailed study of the anatomy and development of one mammal.

The scope of the work is so wide that the reader cannot expect to find accuracy in every detail, or a freedom from time-worn and conventional errors; but, in his preface, "the writer craves the indulgence of those who have directed their special attention to any one of the subjects touched upon," and the impartial reviewer is bound to admit that the merits of the broad view of animal structure given in this book far outweigh its defects, which, on the whole, concern matters of detail only.

But when it is noted that in the second chapter Prof. Wilder properly insists that "the one line of development by which the Primates have become differentiated is in that of their central nervous system, and especially that of the cerebrum" (p. 41), the reader has a right to expect something more than the rather perfunctory account of this system, the influence of which has been paramount in making man what he is. Nor is it too much to expect that a zoologist, even if he has not "directed his special attention" to the question of the distribution of animals, should know that the monotremes do not "occur in New Zealand" (p. 33), and that *Galeopithecus* is not "found in Madagascar" (p. 37)!

In the final chapter a concise and impartial account is given of (a) the Annelid, (b) the Nemertean, (c) Gaskell's (though the name of its author is not mentioned), and (d) the Protochordate theories of the origin of vertebrates; and the author ends his interesting handbook with the quotation from Korschelt and Heider:—"The origin of vertebrates is lost in the obscurity of forms unknown to us. G. E. S.

MAPS OF THE THAMES BASIN.

The Basin of the Thames. (Lettered and Unlettered.) (Edinburgh: W. and A. K. Johnston, Ltd., n.d.) Price 12s. each.

THIS publication consists of two maps, with and without names. The map containing names is well designed and should be of great value for schools.

Contours are shown at 800, 600, 400, 300, 200, and 100 feet, and the areas of equal elevation are distinguished by shades of brown. The rivers are printed in blue, and stand out distinctly from the light brown tints. The names have been carefully selected, only initial letters being shown for towns, while physical names have been printed in a clear but subordinate type. These have followed the lines suggested in a recent map prepared by the Royal Geographical Society.

Local names, such as the New Forest, the Chilterns, the North and South Downs, have been necessarily retained, but to these have been added other names, not so generally well known, but descriptive of physical features. Such are the "Forest Ridges" of

Sussex, Battle Ridge, the Western Downs, the Plain of Selsey, &c. It is to be hoped that these names, which are now generally accepted as being most suitable, will be used in all future maps, as a reasonable uniformity of nomenclature will avoid much confusion in teaching.

Railways, British and Roman roads, and the sites of Roman towns are shown in red. A most instructive lesson will be possible by the use of this map on the difference between ancient and modern lines of communication, and the sites chosen for Roman and modern towns. The map shows clearly that the Roman roads largely followed ridges and avoided river valleys, or, at any rate, kept along the edge of high ground. The Fosse Way, on the eastern margin of the Cotteswold Hills, and the Icknield Way, on the northern slope of the Chilterns, are excellent examples. Most of the Roman towns were situated on higher ground, away from the forests of the valleys, and in positions suited for defence.

The companion map, with no names except initial letters of towns, is disappointing. It was probably essential, for reasons of expense, to keep the representation the same as on the named map, but we feel that it might have been made much more effective if all the contours had been shown from 100 feet to 800 feet, and if the areas they enclose had been marked by clearly defined brown lines. The omission of the 500 feet and 700 feet contour lines means that steep escarpments, such as the southern front of the North Downs, fail to stand out clearly; and the higher valleys, such as those of the Chilterns, are only distinguishable by a close examination of the map. For a map intended for physical teaching the shapes of hill regions are of the first importance, and these need presentation in sufficient detail to give some clue, in connection, of course, with geological maps, to their formation.

It is to be regretted that no county divisions have been placed on the named map. A dotted line, sufficient for reference, would not have spoilt the clearness of the representation and would have been welcome to many teachers.

County boundaries, as studied from political maps, have certainly played too important a part in past teaching, but the regions which they define cannot be ignored in any systematic study of the regional geography of England or in that of local geography.

EARLY VIEWS ON INSECT LIFE.

Experiments on the Generation of Insects. By Francesco Redi, of Arezzo. Translated from the Italian Edition of 1688 by Mab Bigelow. Pp. 160. Portrait, facsimile of original title-page (1768), and 29 plates, besides illustrations in the text. (Chicago: Open Court Publishing Co.; London: Kegan Paul and Co., Ltd., 1909.) Price 2 dollars.

IN the early days of modern science much pioneer work had to be done in clearing away all manner of crude notions and legends, partly based on ideas and faulty explanations of facts or fables handed down from classical times, and partly on popular notions of later date. More than any writer of his period, Redi,

physician to the Court of Florence, and also a poet of considerable eminence, set himself to refute the old doctrine of spontaneous generation, and was mainly instrumental in proving that maggots, &c., did not arise spontaneously in the surroundings where they are met with, but originate from eggs deposited by the parent insect. In fact, Redi accomplished a similar service to science to that performed by Darwin and his coadjutors in our own time, when they gave the death-blow to the analogous doctrine of special creation, though, in the latter case, the task was much more difficult, depending rather on logical inference from facts than on actual experimental demonstration.

We are glad to welcome a translation of one of Redi's most important works, his "Esperienze intorno alla Generazione degli Insetti," which attracted much notice at the period, and went through many editions in Italian and Latin between 1668 and 1688, and was reprinted frequently afterwards in his collected works.

After setting forth various classical theories of the origin of life on the earth, Redi continues:—

"Although content to be corrected by anyone wiser than myself, if I should make erroneous statements, I shall express my belief that the Earth, after having brought forth the first plants and animals at the beginning, by order of the Supreme and Omnipotent Creator, has never since produced any other kind of plants or animals, either perfect or imperfect; and everything which we know in past or present times that she has produced, came solely from the true seeds of the plants and animals themselves, which thus, through means of their own, preserve their species. And although it be a matter of daily observation that infinite numbers of worms are produced in dead bodies and decayed plants, I feel, I say, inclined to believe that these worms are all generated by insemination, and that the putrefied matter in which they are found has no other office than that of serving as a place, or suitable nest, where animals deposit their eggs at the breeding season, and in which they also find nourishment; otherwise, I assert that nothing is ever generated therein."

In proof of these statements, Redi proceeds to describe the breeding of flies from maggots found in dead animals, dung, fruit, &c. He also discusses the question of the bees in the carcase of Samson's lion, and thinks that they made their hive in the dried skeleton; an explanation which is perhaps not quite impossible, though the general view nowadays is that in this (as certainly in some other cases where bees are supposed to have been generated from dead carcasses) the insects were not bees, but flies (*Eristalis tenax*), which were mistaken for them.

In a similar manner, Redi discusses the origin of wasps and scorpions; the effect of the sting of the latter; the cannibalism of lions; the habits of spiders; the breeding of frogs, and the tenacity of life in Mantis. He was, however, puzzled by galls, the insects from which are very difficult to rear; and was much perplexed about their origin. The last portion of the book discusses lice and other animal parasites. The illustrations of these and other animals are excellent, especially considering the period at which they were produced.

OUR BOOK SHELF.

(1) *Smithsonian Mathematical Tables. Hyperbolic Functions.* Prepared by G. F. Becker and C. E. Van Orstrand. Pp. li+321. (Washington: Smithsonian Institution, 1909.)

(2) *Tafeln für numerisches Rechnen mit Maschinen.* Herausgegeben von O. Lohse. Pp. vi+123. (Leipzig: W. Engelmann, 1909.) Price 12 marks.

(1) THE increasing importance of hyperbolic functions in several branches of science and technology has led the Smithsonian Institution to furnish the computer with a more complete set of tables of these functions than was previously available. In the handsome volume before us are printed the natural values to five decimal places of the hyperbolic sine, cosine, tangent, and cotangent of u expressed in radians. The argument u advances by ten-thousandths from 0 to 0.1, by thousandths from 0.1 to 3.0, and by hundredths from 3.0 to 6.0. The logarithms of the above values are also given in separate tables. In order to facilitate interpolation the first derivatives of the functions multiplied by the tabular interval are tabulated in units of the last decimal place. To meet the rare cases in which higher values than six radians occur in calculations, some very high values of $\exp(\pm u)$ are appended to the seven-place tables of the exponential and its logarithm which are printed later on in the volume. To aid the computation of hyperbolic functions of complex variables, such as $\sinh(u \pm iv)$, the values of the circular functions $\sin u$ and $\cos u$, and of their logarithms to five decimal places, are provided with u expressed in radians. Tables are also provided of the gudermannian of u to seven places in radians, and also in degrees, minutes, and seconds. A few supplementary tables are printed for the convenience of the computer, one of which gives the natural logarithms of numbers from 1 to 1000, and another provides for the conversion of radians into angular measure and *vice versa*.

In preparing this volume a good deal of independent computation has been necessary in order to attain completeness and accuracy. In the introduction there is a useful compendium of formulas and integrals involving hyperbolic functions.

(2) Prof. Lohse, of the Astrophysical Observatory, Potsdam, has published these tables of reciprocals in order to simplify and extend the use of calculating machines in scientific computations. These machines deal readily with addition and multiplication, but in order to grapple with division it becomes necessary to take first the reciprocal of the divisor and then to multiply, e.g. to exhibit $n \div 1.759$ as $n \times 0.5685$. In this volume we have provided for us five-place values of the reciprocals of the natural numbers from 1 to 5000, and of the reciprocals of the trigonometrical functions of angles from 0° to 90° for every hundredth of a degree. Appended to the above are a few shorter tables, the most important of which is one of square roots, giving the values of $\sqrt{a}$ and $\sqrt{10a}$ side by side, very conveniently, for values of a from 1 to 1000.

Lehrbuch der praktischen Physik. By F. Kohlrausch. Elfte Auflage. Pp. xxxii+736. (Leipzig: G. B. Teubner, 1910.) Price 11 marks.

It is not necessary in general to say anything in praise of a book which reaches its eleventh edition, but there are special circumstances accompanying the appearance of the eleventh edition of the late Prof. F. Kohlrausch's "Lehrbuch der praktischen Physik" which justify a few remarks. In the first place, the preparation of this edition was one of the latest occupations of its author, who died in January (see NATURE, February 3), a few days after its appearance. Through-

out the forty years the work has been in the hands of students of physics, it has remained the pet child of its creator, and every page bears evidence of the care he bestowed on it. In the work of revision for the present edition, Kohlrausch was assisted by a number of his former pupils, now distinguished for their researches in special branches of the subject, so that it embodies the experience of the leading physicists in Germany. As an example of a section of the book only possible under a system of collaboration of this kind, that on radio-activity, by Prof. E. Dorn, may be mentioned as of special value. As a result, we have a book thoroughly up-to-date, which, as a work of reference for the physical laboratory, stands in a unique position, both on account of the large amount of valuable matter it contains, and for the completeness of its references.

In the second place, the author gives us in the preface a glimpse at the physical laboratories of Germany fifty years ago. There were then about two dozen professors of physics, a dozen assistants, and possibly about two dozen senior students engaged in research in the whole of the country. Apparatus was scanty, and had to be purchased out of a very meagre annual grant. A new professor who could bring with him his own apparatus, was regarded as a special windfall. Systematic instruction in practical physics was given at Königsberg, Berlin, and Heidelberg Universities only, but the need for better organisation of the universities in this respect soon became pressing, and was met by the appointment, in the later 'sixties, of a number of professors who had received their practical training in the above laboratories under Neumann, Magnus, and Kirchhoff. The change which has come about since then is remarkable. There are now many single laboratories in which a greater number of senior students are engaged in research than were so occupied in the whole of the laboratories of the country half a century ago.

The Schoolmaster's Year-book and Directory, 1910. A Reference Book of Secondary Education in England and Wales. Pp. lxxi+448+700. (London: The Year-book Press, c/o Swan Sonnenschein and Co., Ltd., 1910.) Price 7s. 6d. net.

THIS is the eighth annual issue of what has become an indispensable source of information to the educational worker. It consists of three parts, containing respectively general information, alphabetical lists of secondary schoolmasters, and a list of secondary schools. We are able to say from experience that the educational particulars provided by this work are accurate and up-to-date. Among new features of the book this year are important alterations in the section dealing with county and borough education authorities. It is interesting to note that the directory now contains more than 14,000 names, and that the list of secondary schools numbers about 1500. Altogether, the book deserves a wide circulation.

Egypt and the Egyptians. By the Rev. J. O. Bevan. Pp. xxii+224. (London: George Allen, 1909.) Price 5s. net.

THIS is a compilation of miscellaneous information about "Egypt and the Egyptians, their History, Antiquities, Language, Religion, and Influence over Palestine and Neighbouring Countries," written in old-fashioned style. It has no particular plan, and meanders about from one subject to another, but not unpleasantly. Sir G. H. Darwin, who disclaims "anything more than the superficial knowledge of Egypt which is open to any hurried tourist," has done Mr. Bevan the honour of writing a preface to his little book, which will no doubt give considerable pleasure, and convey a good deal of information and instruction to many readers.

The Term "Radian" in Trigonometry.

DR. THOMAS MUIR, in his letter in NATURE of April 7 (p. 156), corrects the misapprehension implied in the "New English Dictionary," viz. the supposition that the word "radian" was first introduced in the "Treatise on Natural Philosophy" by Thomson and Tait.

Dr. Muir says he used the word in 1869 in St. Andrews, and goes on to say that it was after conversation with my father, the late Prof. James Thomson, in Glasgow, that the word was finally adopted in 1874.

I should like to point out that my father adopted the word some years before he came to Glasgow and before he met Dr. Muir. I have a memorandum in my father's writing saying that this name was proposed by him in July, 1871, and it appears in the printed examination questions set by him in the general class examination in Queen's College, Belfast, on June 5, 1873, and published, I believe, in the college calendar.

I well remember several conversations between my father and Dr. Muir with regard to the use of this and other words, but "radian" had already been adopted publicly by my father, and apparently had been already independently used by Dr. Muir.

JAMES THOMSON.

The Yellow Colour in the Stoat's Skin.

IN her letter to NATURE of March 24 Miss I. Sollas remarks on the "canary-yellow" colour "in members of the stoat family when the winter whitening is incomplete," adding, "there can thus be little doubt that the yellow body produced artificially in the fur of the albino rat is a substance similar to the yellow pigment of the stoat's winter coat. . . ." I do not know whether it has been recorded, though I should have thought so, that a stoat's fur of the purest white will, after exposure to light in a museum case for a time, varying with the intensity of the light, invariably turn distinctly yellow—fainter, however, than "canary-yellow." I have made no chemical or microscopical examination of fur so yellowed, but the usual reason assigned for the change is the absorption by the hairs of a small amount of fat out of the skin, induced by the light and heat of summer. I understand, also, that ermine kept in a dark chamber or box the temperature of which is high will also turn yellow. Stoats in this part of the country often become white early in the season before any real cold weather has occurred.

Transit of Halley's Comet across Venus and the Earth in May.

I BEG to direct attention to the following:—

It is my intention, at Kaafjord, in Finnmarken (in the north of Norway), together with my assistant, Mr. O. Krogness, to take magnetic and atmospheric observations during the period May 7 to June 1 next in connection with the transit of Halley's comet across the sun's disc on May 18-19.

It is conceivable that the tail of the comet may consist chiefly of electrical corpuscular rays; and, if this be so, we should expect that these rays, owing to earth-magnetism, would be drawn in, in the Polar regions, in zones analogous with the aurora zones, assuming the tail of the comet to be of sufficient length to reach the earth.

These rays will then, in such a case, exercise, amongst other things, magnetic influences and electric inductionary effects, especially strong in the Polar regions, and it is particularly such effects we are desirous of tracing. The tail of the comet, if it should consist, as above assumed, of such radiant matter, will alter its shape at a very considerable distance from the earth, and we may expect to

see similar formations of light to those which occur during my experiments with kathode rays around a magnetic terrella.

In my work, "The Norwegian Aurora Polaris Expedition, 1902-1903," descriptions will be found in several places of these phenomena, but to elucidate the subject here I append a few new illustrations, which show very plainly the shape of these formations of light.

Figs. 1 and 2 show how the rays are drawn in in belts around the magnetic poles of the terrella, corresponding

February, p. 57), and it is not impossible that indications of an alteration in those parts of the comet's tail nearest the planet may be noticeable.

We may then possibly expect to find traces of the rays being drawn in towards the polar regions of Venus in a manner similar to that demonstrated by the experiment shown in Fig. 4, or a more or less distinct bending of the comet's tail, assuming Venus to be magnetic.

The probability of such being visible must, however, be admitted to be small, as the central line or the tail, if it

FIG. 1.

FIG. 2.

FIG. 3.

with the polar-light zones on the earth. They are taken looking along and perpendicular to the magnetic axis. Fig. 1 shows the spiral rings of light around a magnetic north pole, corresponding to the south pole of earth magnetism. We find these belts of light sometimes, as here, with a tolerably even strength of light like a continuous band, and at other times we find the rays concentrated in three limited streaks, with well defined positions around the magnetic poles of the terrella.

Fig. 3 also shows an equatorial ring. This phenomenon of light is magnificent, but unstable; it is difficult to produce; it may suddenly appear and suddenly vanish, as the rays which run round the terrella at the equator are difficult to obtain sufficiently concentrated for the rarefied gas to illuminate them. At the lower part of Fig. 3 and on Fig. 4 a characteristic pointed tongue of light will be seen, which is drawn in, and shows the manner in which the rays here come into the terrella. The magnetic equator is indicated on the terrella by a dark line.

FIG. 4.

It may now be imagined that analogous formations of light may be observable around the earth of the rays from the comet's tail on May 18-19. The downward rays in the Polar regions will, it is true, be difficult to observe in northern parts owing to the northern declination of the sun, but in Antarctic regions there may be more hope of doing so, and the phenomenon would then probably appear somewhat similar to the aurora australis. At night, in low latitudes, one may conceive the possibility of a ring like the equatorial ring being observable.

About May 2 the comet will be in the vicinity of Venus (see *Bulletin de la Société astronomique de France*,

is directly away from the sun, will be at a considerable height above the planet; but I desire, nevertheless, to direct the attention of astronomers to these conditions, as Venus, if as strongly magnetised as our earth, must be expected to exercise a noticeable influence on the tail of the comet at a distance of several million kilometres, especially if the rays in the tail are easily deviated by magnetic force.

This phenomenon may, in case it is present, be determined by astronomical observations of the comet's tail and Venus in the period May 1-3, and I beg, therefore, to ask astronomers, in the interests of science, to make arrangements for the necessary observations, if possible, and to favour me with a short account of the results.

Neutral Doublets at Atmospheric Pressure.

In his papers on magneto-kathode rays, Prof. Righi assumes the presence of neutral doublets, formed of a positive and negative ion in more or less stable combination. Sir J. J. Thomson has independently put these in evidence very clearly in his experiments on positive rays. Working independently, we have made some observations which point to the existence of such doublets at atmospheric pressure. Ionised gas is drawn through two insulated metal tubes; along the axis of each a thick insulated wire electrode is fixed. These wires can be connected in turn to a Dolezalek electrometer, and the current between tube and electrode measured. The ionised gas is produced by splashing mercury, or by heating lime or aluminium phosphate on a strip of platinum foil. With a certain blast, in one case, the current reached its saturation value on the first electrode with a voltage of 320, being then 130 in arbitrary units. Raising the voltage to 656 did not increase this by one division; the extreme readings at the intermediate voltages were 128 and 130, so that the observations were quite regular. Nevertheless, with 656 volts on the first electrode a current can be detected at the second, this in some cases amounting to as much as 10 per cent. of the original.

Lime gives a large excess of negative, mercury, and aluminium phosphate of positive, ions, but in each case

tried the currents on the back electrode were practically the same, independently of the sign, while the same ionising agent was used. The saturation curves also present a peculiarity in a large number of cases. The curves become nearly horizontal at about 240 volts, after which they rise again rather rapidly, and finally become flat at about 320 volts. Each of these results is readily explained if we assume the presence of neutral doublets, which are broken up either by collisions or by the action of the field. Further experiments are being made.

The Etiology of Leprosy.

IN NATURE of April 7 I have read with interest the article on Dr. Ashburton Thompson's report on "Leprosy in New South Wales." In that report Dr. Thompson (one of our foremost authorities) has repeated a statement made in several of his former papers avowing distrust in the doctrine of contagion and in the efficacy of isolation as a preventive measure. In commenting, with surprise, on his opinion, the writer of the article says:—"One would have thought that the success which has attended the practice of isolation in Norway during the past forty years afforded sufficient evidence of its value even to the most sceptical."

Now I am quite with Dr. Thompson in his opinion, and must ask to be allowed to state in the clearest possible terms that not only is there no reason to believe that attempts at isolation have taken any share whatever in the diminution of Norwegian leprosy, but much to the contrary. That the disease has declined, and continues to decline, is happily true. The *propter hoc*, however, fails utterly when we recognise that there has been during this period of its decline no increase whatever in isolation. There has never been in Norway any isolation directed against contagion. The first large leper hospitals in Norway were built by those who did not believe the disease contagious (Dr. Danielsen and others), and who wished simply to prevent marriages and to provide comfortable homes. When the bacillus was discovered, the old theory of contagion was revived, and subsequently certain legal enactments were passed, but there was no increase in arrangements for isolation. Quite the contrary. From that day to this the number of those isolated has been progressively reduced. The lepers have been left at home with their relatives. Yet the disease has declined. It may be noted that it was declining before. It must be obvious that it has been dying out under some other influence, and that the asylums, which no one had thought it worth while to provide, could not possibly be the cause. Let me in passing just remark that during the same period a parallel effort for the extirpation of leprosy was being made in South Africa. There efficient isolation laws were passed, and plenty of accommodation provided. Without flinching, compulsory isolation was carried out. The result has shown a steady and alarming increase in the disease.

Compulsory isolation has never been attempted in Norway, and it has been rigidly enforced in South Africa. The results have been conspicuously opposite to what believers in contagion would expect. The true explanation in each case is, I believe, not difficult to give, but I must not intrude upon your space further than simply to assert that it has nothing to do with belief in contagion and attempts at isolation. Dr. Thompson is, I think, more than justified in the doubts which he has expressed, and it rests with those who in future quote the Norwegian facts to show that they really bear the interpretation which they give to them.

JONATHAN HUTCHINSON.

SIR JONATHAN HUTCHINSON'S views on the etiology of leprosy are well known to be opposed to the generally accepted view that it is an infectious disease caused by Hansen's bacillus. They were again brought before the second International Conference at Bergen, August 16-19, 1909. Nevertheless, the conclusions carried by the delegates were opposed to them. The second International Scientific Conference for the suppression of the disease reaffirmed in all aspects the conclusions adopted by the first confer-

ence in Berlin, 1897, when the attitude of Dr. Ashburton Thompson towards the accepted etiology was before the delegates. Leprosy was affirmed to be a disease communicable from one person to another. No country, no matter what its geographical situation may be, is secure against infection, and the adoption of proper measures against this possibility was recommended:—"Having regard to the favourable results which have been obtained in Germany, Iceland, Norway, and Sweden, by isolating the patients, it is desirable that infected countries should adopt the same measures."

In Norway the law, as formulated again in 1885, gave the Sanitary Commission or Board of Health in each district the right to order a leper, if he will live at home, to have his own room—at least his own bed; his clothes ought to be washed separately; to have his own eating apparatus—spoon, fork, knife, &c. If he cannot, or will not, conform to this regimen, he is obliged to enter an asylum. There are those who hold that leprosy is less easily communicated from the sick than is consumption. Dr. Thompson apparently implies that "special precautions therefore seem to be unnecessary" in leprosy because in the past they have been ignored for tuberculosis; but, in the opinion of the writer, it would be of enormous advantage to the public weal if the regulations as applying only to lepers remaining at home could be enforced in regard to tuberculosis. As a matter of fact, the success of the leprosy laws in Norway has led, on the initiative of Dr. Claus Hansen, brother of the discoverer of the *Bacillus leprae*, to the enforcement of analogous regulations as prophylactic measures against tuberculosis in that country since 1900.

It alters nothing in the efficacy of segregation that it was applied in Norway by Danielsen before Hansen—Danielsen's pupil, I believe—had discovered the lepra bacillus. Nor will any useful purpose be served by discussing the efficacy in the application of the law of segregation in Norway as impugned by Sir Jonathan Hutchinson. Dr. Ashburton Thompson's criticisms had been carefully studied by the writer of the article and passed in silence as special pleading—moderate, able, even eloquent—but as unconvincing to him as they have been to the expert delegates at two successive international conferences, the second of which was held in Norway itself.

THE WRITER OF THE ARTICLE.

Auroræ Display.

THERE was a very fine display here of the aurora between 8 and 9 p.m. The nature of the phenomenon was sufficiently clearly marked to deserve more than a passing notice.

The curtains and shafts of light all had their origin overhead, radiating from a point a few degrees to the north of Castor and Pollux. At times as many as five curtains of light could be seen close together near the radiant centre, some of them spreading over the southern and others over the northern sky. When viewed to the north or south the thin veils showed streaks of light all radiating from the point of origin overhead. When viewed towards the east or west, i.e. end on, the light was most brilliant, and the wavy nature of the hanging curtains of light most marked.

For at least an hour these curtains or hanging veils of light could be seen originating above and spreading in all directions, north, south, east, and west. The radiating effect was, of course, due to perspective. There was very little wind at the time, and the curtains of light seemed to travel with it. Another effect which was most marked was that the east and west end of a curtain descending to the north of the point of view curved towards the north, whilst the ends of those curtains which descended to the south of the point of view of the observer curved to the south. This curving only showed itself when the curtains were low down and losing their brilliancy. There could be no doubt but that the whole phenomena originated in a comparatively small area to the north of Castor and Pollux.

The day had been fine and bright, and the ground was free from snow. Towards half-past nine the sky became hazy.

THE FREE ATMOSPHERE.¹

THE publication referred to below adds yet another to the series of memoirs issued by the Meteorological Office in the past few years. It furnishes an example, of comparatively rare occurrence in original scientific investigation, of the successful cooperation of private and official enterprise.

The introduction by Dr. Shaw contains a short historical account of the progress made in the investigation of the upper air and a summary of the more important results obtained. It includes a welcome bibliography of the chief English publications on the subject.

The work in this country was begun so long ago as 1749 by Wilson and Melville, of Glasgow, and the balloon ascents of Jeffries, and, later, of Welsh and Glaisher, maintained our position in the forefront of upper-air research. After a period of comparative inaction, the investigation was renewed at the instigation of Mr. Dines at the beginning of the present

6 inches midway between them. This kite is used if the wind aloft is likely to exceed 40 miles per hour. Steel piano wire, $\frac{1}{32}$ inch in diameter, having a breaking strain of 250 lb., is used with all the kites.

If, when a kite is flying, it appears probable that putting on more kites, or letting out more wire, will increase the strain to more than 100 lb., the attempt is not made owing to the risk of breaking the wire, especially as records from greater heights can be obtained with registering balloons. It ought, however, to be borne in mind that the results for temperature and humidity obtained by balloons are less trustworthy than those obtained by kites, and this is of especial importance in connection with the daily variations. A kite can be kept for some time at a nearly constant level, and the kite and instruments remain exceptionally well ventilated without artificial means.

Dines's use of embroidery cambric at 9d. per yard, and black dress lining at 5d. per yard, for his sails recalls Stokes's marked preference of candles for his optical experiments. The art of using the simplest

A

B

FIG. 1.

century. Dines began his work on the west coast of Scotland in 1902-4, and continued it, first at Oxshott, 15 miles south-west of London, and afterwards at Pyrton Hill, 40 miles west by north of London.

The report deals with kites, pilot balloons, and registering balloons, and contains a summary and brief discussion of the results obtained.

Three kinds of kites, all of the box pattern, are used at Pyrton Hill. No. 1 is 9 feet high, and has sails 3 feet wide and 18 feet long. It is used in light winds. No. 2, for standard use, is very similar, but the sails taper from 3 feet at the front and back sticks to 2 feet 4 inches at the sides. No. 3 is only 7 feet high, and the sail edges form arcs of circles, the width of the sails being 2 feet 6 inches at the sticks and 1 foot

things to the best advantage runs some danger of being lost in the laboratories of ready-made apparatus and "arranged" experiments. It is refreshing to find instances of it in an official publication.

A good deal of trouble is taken to make clear, by diagrams and description, the method of letting-out and winding-in the kite wire. Mr. Dines having discovered, by long practical experience, the places where difficulties arise has taken the trouble to invent the necessary safeguards and to give to others the benefit of his labours.

The meteorograph used with kites is shown in Fig. 1, A, B; Fig. 1, B, shows the exposed under-surface of the apparatus. The separate parts are (1) the lever and thread of the anemometer; (2) the thermometer, a spiral metal tube containing spirit; (3) the clock; (4) the cover of the aneroid barometer; (5) a metal cover protecting the hair of the hygrometer. In Fig. 1, A, the recording pens are (1) humidity, (2) atmospheric pressure, (3) temperature, (4) wind velocity. The surface shown in Fig. 1, A, is covered by waterproof cloth

¹ M.O. 202. "The Free Atmosphere in the Region of the British Isles." Contributions to the Investigation of the Upper Air, comprising a Report by W. H. Dines, F.R.S., on Apparatus and Methods in use at Pyrton Hill, with an introduction and a note on the Perturbations of the Stratosphere by Dr. W. N. Shaw, F.R.S., Director of the Meteorological Office. Pp. iv+56. (London: H.M. Stationery Office, 1900.) Price 2s. 6d.

when in use. The instrument is tied in the middle of the kite, partly for convenience, partly, presumably, to shelter it from direct sunshine.

The record is made on the cardboard disc shown in

FIG. 2.

Fig. 1, A. The difficulty of procuring cardboard which is not warped by varying humidity, and the occasional thickening of the trace through the running of the ink, suggest that it would be an improvement to use a smoked metal sheet.

The anemometer deserves special mention because it is simple and unique. It consists of a light celluloid ball of 3 inches diameter suspended by about 40 feet of fine cotton, and the velocity of the wind is deduced from the tension in the cotton. The effect of the wind on the cotton is neglected, but it appears doubtful if this is justifiable. With cotton 0.2 mm. in diameter, the area exposed to the wind is nearly one-third that of the ball used.

Pilot balloons are usually small balloons 2-3 feet in diameter, which are sent up to determine the wind at different altitudes. Observations are made by theodolites at the end of a base line, or at times by one theodolite, the rate of ascent in that case being calculated from the free lift and diameter of the balloon.

It is assumed that the rate of ascent is given by

$$L = k\rho\tau^2r^2 = \mu v^2r^2,$$

where L is the free lift, r the radius of the balloon, v the upward velocity, ρ the density of the air, and k a constant. The values of μ , calculated from ten sets of observations given in the report, show great irregularity, varying between 5.5×10^{-4} and 15.6×10^{-4} in C.G.S. units, or between 1/480 and 1/170 in the units used in this part of the report (grains, feet, minutes). Unfortunately, no information is given, and no reasons are put forward, to account for the variations, beyond a vague suggestion of convection currents. It would be interesting to know how much of the variation could be attributed to (1) the deposition of dew on the balloons, (2) the effect of solar radiation on the balloon's temperature, (3) differences in the wind, (4) errors in the observations. As they stand, the results indicate that observations made with one theodolite may give very erroneous values for the wind.

An interesting table gives the values of μ^{-1} obtained by six different methods. From his experiments with

a whirling machine, Dines found 240. Observation of a small 3-inch ball, falling through 200 feet, gave 280. Dines's theodolite observations give 290, those of C. H. Ley 330, and twelve ascents of registering balloons 322. Stanton found a still higher value, 354, from laboratory experiments on a 1½-inch ball. It is of interest to note the close approximation to the corresponding value, 380, deduced from the value of k given by Allen's experiments with steel balls in water.

Registering balloons of about 1 metre diameter, having a free lift of 200 to 300 grammes, are used to carry a meteorograph, which weighs, with its case, 60 grammes only (28 grammes without the case). About 60 per cent. of the balloons sent up are recovered, and it seems remarkable that the proportion is higher in winter, the season of high winds, than it is in summer. The explanation given is that when the meteorographs fall in standing crops they frequently come into contact with mowing machines, and as the instrument case resembles an old tin can it is not surprising that Hodge neglects to gather up and return the fragments. The difficulty might be overcome by attaching a partially filled small, cheap balloon, which would act as a signal for some time after the instrument reached the earth.

An addition of 5 per cent. to the number recovered would compensate for the extra cost.

The meteorograph is shown in Fig. 2, and diagrammatically in Fig. 3. The aneroid box A expands under decreasing pressure and opens the frame in which it is fixed, so that E, L move across the plate beneath them. If the temperature is constant they make two parallel traces; if the temperature falls, the German silver strip M contracts more than the invar strip HC, and rotates DE about C. Thus, the abscissæ of the trace give the pressures, and the distance between the traces the corresponding temperatures. The instrument furnishes no information as to the rate of ascent.

It is a great advantage that the calibration of the instrument is made on the actual plate, which is fitted ready for the ascent, and that the pressure and temperature are varied together. It ought, however, to be explained why the instrument is tested down to -40° C. and to 100 mm. only, when it is to be exposed to temperatures of -60° C. and pressures of 50 mm. or less.

The heights have been obtained from the recorded pressures by the use of diagrams, and more recently by means of semi-logarithmic squared paper. The need for great care in dealing with this problem is illustrated by the errors in the table on p. 7. On July 29 the difference of pressure

FIG. 3.

between 11 and 12 km. is 20 mm. at Manchester and 28 mm. at Pyrton Hill, which has a higher temperature at that height. Similar differences occur between 13 and 14 km., and between 5 and 6 km.

Great difficulty is experienced in reconciling the temperature observations with the observed and expected decrease in wind velocity in the advective region. The obvious errors noted above may be partly responsible for the extraordinary velocity of 150 m.p.s., found from the horizontal gradient of pressure at 16 km. But apart from errors of calculation, an error of only 1°C . in the mean temperature of the air column would produce an error of nearly 3 mm. in the pressure at 16 km. It must also be remembered that where convection is prevented the condition of steady motion may never be reached, and the differences of pressure may be equalised by translation of air across the isobars with moderate velocity.

Dr. Shaw finds that if the lower surface of the advective region is depressed owing to a disturbance in the lower atmosphere, there will be an increase of temperature of 9°C . per km. of depression. Such a depression would presumably be propagated with the same velocity as the disturbance, but the obstacles to convection in the advective region may make the upper portion of the atmosphere act as a damping agent by which the disturbance would be annulled.

The mean, maximum, and minimum values of H_c and T_c , the height and temperature at which the advective region begins, are given in the table:—

	Mean H_c	Mean T_c	H_c	T_c
Manchester 11'6 km.	219' A		Max. 15'2 km.	241' A
Pyrton Hill 12'0 "	217' "			
Ditcham ... 12'2 "	221' "		Min. 7'8 "	224' "
Crinan ... 11'0 "	226' "			

The values are higher than the mean values found by the present writer and Harwood. The difference probably arises partly through the method of fixing H_c , partly owing to the exclusion of the 1909 results from the present report.

It is a pleasure to note that pressure is expressed in megadynes per cm^2 , and temperature in degrees C . above the absolute zero. The report is full of interest to all engaged in upper-air research, and will be especially useful to those who are contemplating the establishment of new experimental stations.

THE HISPAR GLACIER.¹

DR. AND MRS. BULLOCK WORKMAN, the well-known explorers of the higher Himalayas, have read before the Royal Geographical Society a most interesting account of the Hispar Glacier. This is one of a group of four of the world's greatest mountain-glaciers, which, together with two others of them—the Biafo and the Chogo Lungma—and some of their tributaries, have been explored from end to end by these indomitable climbers. The Hispar Glacier, one of the many feeders of the Indus, occupies a long and nearly straight valley, running roughly parallel with the crest of the Karakoram—one of the

¹ The Hispar Glacier. I. Its Tributaries and Mountains. By Fanny Bullock Workman. II. Prominent Features of its Structure. By William Hunter Workman. (*Geographical Journal*, vol. xxxv., pp. 105-37, February, 1910.)

watersheds of Asia. Here that is gashed by rather short and steep transverse valleys, altogether nine in number, and attains an elevation often exceeding 20,000 feet above sea-level. On the southern side is another mountain wall, not quite so lofty, though even its lowest point is quite a thousand feet above the summit of Mont Blanc. From its western part—rather more than fifteen miles in extent—six tributary glaciers—three of them large—descend to the Hispar, but its eastern and upper portion—fully twenty-one miles in length—is practically unbroken. A rather long and flat snow saddle, 17,500 feet above sea-level, parts the Hispar from the Biafo Glacier, which descends towards the south-east, and the total length of the former, from its termination near Hispar village, at a height of about 11,000 feet above sea-level, is, according to Dr. Workman's measurement, a little less than thirty-seven miles, or a mile and a half greater than that assigned to it by Drs. Calciati and Koncza.

The pass over the Hispar and Biafo glaciers, according to Lieut.-Colonel Godwin-Austen, who,

FIG. 1.—A glacier-table of unusual size met with on the lowest third of the Biafo Glacier at an altitude of about 3660 metres (12,000 feet). The rock-boulder was 5 metres (16'4 feet) long, the ice-pedestal 3'8 metres (12'46 feet) high, and the height of the whole 5'5 metres (18 feet). A table with much lower pedestal seen in distance at left. (From the *Geographical Journal*.)

about half a century ago, explored these ice-clad fastnesses, was in former times occasionally used by natives, especially marauders, but when Sir Martin Conway traversed it in 1892¹ he found the traditions were very vague. The only serious difficulties are those due to the length of the journey at such a considerable height above sea-level. These, however, did not prevent Dr. and Mrs. Workman from spending several weeks on their way over the pass from Hispar village to Askole, and carefully studying this ice-clad region.

The Hispar Glacier has a low gradient—on the whole about one in thirty—and its average width is a little less than two miles. It receives, as has been said, six large tributaries from the northern side, and three, also large, on the lower part of its southern side. All, and especially the former, are laden with debris to an unusual extent. The effect of this is

¹ See "Climbing and Exploration in the Karakoram-Himalayas," by W. M. Conway, chapters xvi-xix. (1894.)

plainly visible on the trunk stream. Here, for a distance of nearly fifteen miles above its end, the whole surface "is broken into ice hillocks, separated by deep depressions and heavily coated with debris of every size from mud and sand to granite blocks 20 to 50 feet in diameter," such as may be seen in the gigantic glacier-table, for the picture of which (Fig. 1) we are indebted to the Royal Geographical Society. From slightly below the entrance of the Haigatum tributary a band of white ice appears among these hillocks, which broadens out as it rises until it occupies all the southern side of the glacier. On the northern side the hillocks persist for eleven and a half miles farther up. They vary in height from about 50 to 230 feet, or even more, and sometimes recall drumlins in their linear arrangement and form. Beyond these hillocks the ice, as would be expected, is fairly free from debris. In the other parts, while the lateral moraines are large, medial moraines are practically absent.

The surface exhibits some other peculiarities. Over two-thirds of its area lakelets; occupying ice-basins,

Hispar and its tributaries, as may be seen in Fig. 2. Intra-glacial moraines, due to the excretion of debris which has been engulfed in large crevasses, may also be observed, as well as the usual structures of *névé* and glacier-ice.

The scenery of this region of snowy peaks and giant glaciers has a general resemblance, though on a grander scale, to that of the Alps and the Caucasus, and its dominant outlines are indicative of the action of fluvial rather than of glacial erosion. It is also worth noting that, notwithstanding the trough-like shape of the valley occupied by the Hispar ice-stream, neither the map nor the photographs suggest any marked truncation of the spurs past which it moves. Yet here, where several ice-streams are crowded into a comparatively narrow corridor, we might expect to find its rocky wall even undercut by their struggle to force a passage. The Hispar Glacier was one of several on which in 1906 the Geological Survey of India fixed marks in order to study their advance and retreat. It then appeared to be practically stationary, and had thus continued to the time of Dr. Workman's visit. So, too, had the Yengutsa Glacier, which reaches the valley-floor a little below the end of the Hispar. Yet, about five years prior to 1906, it had rapidly advanced for a distance of nearly two miles. One minor point of interest may be mentioned. Grouped spires or pyramids of snow or ice were not seldom observed, resembling the *nieves penitentes* of the Andes, to which Dr. Workman, though not without protest from Sir Martin Conway, extends the name.

T. G. BONNEY.

FIG. 2.—A border-lake near the junction of the Jutmaru with the Hispar Glacier. It is enclosed by a lateral moraine and the mountain-wall on the right, and the high side of the Jutmaru Glacier on the left, from which the ice-fragments floating on the water are derived. The stratification of the blackened glacial ice is well seen. Behind are the high snow-peaks walling in the Jutmaru. (From the *Geographical Journal*)

are unusually common. Thus, as might be anticipated, it is but little crevassed. In fact, the only ice-fall is at the beginning of the descent from the actual pass, where the subglacial valley floor naturally steepens. In these circumstances the "hummocky" surface appears at first sight anomalous, but of this Dr. Workman offers a satisfactory explanation. The trunk stream of the Hispar receives at least a dozen tributary glaciers, most of them large. The valley, however, is a trench of only moderate breadth, bounded by steep, rocky walls. As the side streams are too strong to be ponded back by the main one, they force their way downwards side by side with it. Thus the pressure becomes greater than the resisting power of the ice, and this is squeezed upwards into ridges and protuberances. These are favourable to the formation of lakelets, which extend up to an elevation of about 16,000 feet, surface streams being correspondingly rare. Other lakelets, formed by dams of ice or moraine, occur at the side of the

HALLEY'S COMET.

SINCE its conjunction with the sun Halley's comet has been seen from several observatories, and on April 16 was seen with the naked-eye by the observers at Cape Town. Thus there is some reason for hoping that, given clear morning skies, the comet may become easily observable in England, although its low altitude at sunrise, until after it has transited the sun on May 19, is not favourable.

The following is part of the ephemeris calculated for April and

May by Dr. Smart, and communicated by Mr. Crommelin to the *Astronomische Nachrichten* (No. 4379):—

Ephemeris for Greenwich Noon.

1910	R.A.	Decl.	1910	R.A.	Decl.
	h. m.			h. m.	
April 24 ...	23 50.3	+ 7 47	May 20 ...	5 3.4	+ 19 8
28 ...	23 50.9	+ 7 56	21 ...	6 9.9	+ 17 40
May 2 ...	23 54.5	+ 8 18	22 ...	7 3.1	+ 15 14
6 ...	0 3.1	+ 9 5	23 ...	7 44.8	+ 12 40
10 ...	0 21.6	+ 10 30	24 ...	8 18.3	+ 10 24
12 ...	0 38.5	+ 11 41	25 ...	8 40.1	+ 8 31
14 ...	1 5.8	+ 13 27	26 ...	8 58.9	+ 6 59
16 ...	1 49.9	+ 15 59	27 ...	9 13.1	+ 5 45
17 ...	2 23.1	+ 17 29	28 ...	9 24.6	+ 4 45
18 ...	3 7.3	+ 18 51	29 ...	9 33.8	+ 3 50
19 ...	4 3.2	+ 19 43	30 ...	9 41.4	+ 3 15

As will be seen from the ephemeris, the comet, when near the sun, will travel very quickly across our line of vision, traversing Aries, Taurus, Orion, and part of Gemini between May 16 and 22.

On May 20 the distance of the comet from the earth will be about fourteen million miles, but by May 30 this distance will have increased to more than forty million miles.

The two diagrams here given show, roughly, the conditions of observation, Fig. 1 for the eastern apparition, Fig. 2 for the western. In Fig. 1 the stars are shown approximately as they appear to an observer in London looking due E. one hour before sunrise (i.e. 3.30 a.m.) on May 1; the dated circles represent

FIG. 1.

the approximate positions of the comet for the date given. Unless the eastern sky is fairly clear it is questionable whether Venus will be seen. It is obvious that to see the comet during its period as a "morning star" one must get away from the smoke-laden horizon found near large towns, and ascend to as great an altitude as possible. The observation will probably not be a simple one, for at this time of the year the sky, an hour or so before sunrise, is never dark unless cloudy; the dawn comes quite early. For

this morning apparition, the Great Square of Pegasus should act as a splendid "warner" and landmark, just as it did in the evening apparition of comet 1910a. This mutual association of the two comets with Pegasus affords a good example of one of the chief difficulties experienced by those astronomers who have endeavoured to trace Halley's comet amid the mass of brief and very general records of comets in ancient chronicles. Fig. 2 illustrates the conditions after May 20, when the comet will be an evening star; the observer is supposed to be looking due W. at one hour after sunset on May 25 (about 9 p.m.); with a clear horizon, Procyon may serve as the indicator, but in any case Gemini and Leo will afford ready landmarks. It is now the general opinion, and hope, that no chart will be necessary during the last week or so in May, for the comet gives indications that it will probably be bright enough to be seen without difficulty. One favourable point is, of course, that during the morning apparitions the tail will rise before the comet, whilst under the conditions shown in Fig. 2 it will set later.

That the comet has developed a tail of some size is shown by photographs taken at Juvisy on February

12 and at Ottawa on February 10. The former show a thin, feeble tail $1^{\circ} 30'$ long, the latter, which is reproduced in Fig. 3, a tail $\frac{1}{2}^{\circ}$ long. From M. Baldet's drawing, made at the Juvisy equatorial of March 5, it would appear that the southern branch shown by him, Fig. 4, was probably too faint to impress itself on the Juvisy photograph. It is interesting to recall, here, that in the 1835 apparition the comet, for some time after passing perihelion (November 16), showed no trace of the tail, which on October

15 had extended to a distance of 20° . According to Sir John Herschel in his "Outlines of Astronomy," the comet was not picked up, after perihelion, until January 24, 1836, and then presented a small, round, well-defined disc, rather more than $2'$ in diameter.

According to a correspondent of the *Morning Post*, the comet was seen at Greenwich Observatory as a nebulous disc, some $30''$ in diameter, in the 10-inch telescope, on the morning of April 18. A nucleus, from $3''$ to $5''$ in diameter, was recognised, but no definite tail could be seen, probably on account of the approaching daylight; there was, however, a lack of definition, on the western side of the head

probably denoting the presence of the tail. With the 13-inch telescope the comet was followed until 4.25 a.m., and was estimated to be as bright as a second or third magnitude star.

While the chance of capturing a sample of the comet, as suggested by Dr. Allen, is perhaps very small, it is a pity that apparently no action is being taken. The passage of the earth through a comet's tail is so rare an occurrence that even a small opportunity ought not to be missed. In the April number

FIG. 2.

of the *Bulletin de la Société Astronomique de France*, M. C. E. Guillaume suggests the liquefaction of a large quantity of air which could afterwards be treated by fractional distillation, and possibly some cometary matter recognised. He points out that very minute quantities of the rare gases, e.g. krypton, are thus secured from immense volumes of air, and that it is now possible to liquefy 1000 cubic metres of air per hour; as he remarks, it is just possible that by this means the chemical study of the comet

might become a by-product of an industrial operation.

M. Flammarion suggests that if there is any palpable material at so great a distance from the head, it might be possible to measure the minute rise of temperature produced by the earth rushing through it at the rate of 77 kms. (forty-eight miles) per second.

FIG. 3.—Halley's Comet, 1910, February 10. Photographed at Ottawa. 1

The possibility of detecting the nucleus of the comet when it is crossing the sun's disc appears to be very remote. As pointed out by Prof. W. H. Pickering, a solid dark mass would need to have a diameter of at least seventy miles in order to be detected under these conditions, and, from the fact that Herr Archenhold saw a twelfth-magnitude star tran-

FIG. 4.—Halley's Comet, 1910, March 5. From a drawing by M. Baldet.

sited by the comet, on December 5, without changing either in colour or brilliancy, it is extremely unlikely that masses of this order of size are contained in the comet's head; but the Kodaikanal spectroheliograph, in the hands of Mr. Evershed, may be able to disclose the cometary vapours during the transit.

There have been many surmises as to what will be the effect on the earth and atmosphere. Some of these are notable only for their extravagance, but it does seem probable that an exceptional display of aurora may be generated, and also that we may experience the mistiness of the atmosphere which was generally noted in 1861, before it was known that we had passed through the tail of the great comet of that year. It has been suggested, too, that we may see the extension of the tail as a series of diverging streamers, as was also noted in 1861.

Reports from China state that the comet is being used as an omen to inflame the rioters in the disaffected districts, and that the authorities are exhibiting pictures of the comet, with accounts of its previous apparition without ill-effects, in order to reassure the inhabitants. While there is, of course, no possible likelihood of serious misapprehension in this country, it is obvious that there yet lingers a certain amount of superstition concerning the baneful effects of comets. We would suggest to all teachers that the May apparition will afford an excellent opportunity for giving real, "live" nature-study lessons, which should effectively eradicate such superstitious fancies from the minds of the rising generation.

ROMAN BRITAIN.¹

THE first of the two volumes referred to below contains a fully illustrated account of the excavations carried out early in 1907 by the Manchester and District Branch of the Classical Association on the site of the Roman fort at Castlefield, Manchester. The second volume is a supplementary volume by the same association, describing excavations of an earthwork at Toothill, Cheshire, and at the Roman Fort Melandra.

The first volume is something more than a mere dry-as-dust description of excavations. It contains a number of very interesting and informing essays dealing with different departments of the subject, and written by experts, so that the general reader will have no difficulty in understanding the nature and value of the work that has been so efficiently carried out. Both volumes are ably edited by Mr. F. A. Bruton, of the Manchester Grammar School.

An interesting article on the name of the fort, by Prof. James Tait, shows how difficult it is to suggest an etymology of an ancient place-name which will withstand the assault of destructive criticism. The name Mancunium, which is usually associated with the Roman fort at Manchester, has been derived by various authorities from the Welsh, *main*, "a stone"; from the Welsh *man*, "a place," and *cenion*, "skins"; from the Welsh *meini cochion*, "redstones"; and from the Old Celtic *mammion*, suggesting a derivation from *mamma*, "mother." The last derivation applies to the form *Mamcunio*, one of the half-dozen different readings found in various ancient manuscripts.

Among the inscriptions found in the course of the excavations are several on altars dedicating them to the goddess "Fortune, the Preserver." The inscriptions, however, give very little information as to the details of the Roman occupation, though one inscription appears to imply that at one time soldiers from Rætia (Tyrol) and from Noricum formed part of the Manchester garrison.

Among the objects were a considerable number of coins and articles of bronze, silver, iron, and glass.

¹ "The Roman Fort at Manchester." Edited by F. A. Bruton. (Manchester: University Press; London: Sherratt and Hughes, 1909.) Price 5s. net.

² "Excavations at Toothill and Melandra." Edited by F. A. Bruton. (Manchester: University Press; London: Sherratt and Hughes, 1909.)

Among the pottery are some beautiful examples of "Samian" ware, some fine drawings of typical pieces by Mr. Phelps being reproduced.

An illuminating chapter on Mithras-worship in Roman Manchester, written by the Rev. E. L. Hicks, advances the theory that Mithras-worship was encouraged by the Emperors among the Roman soldiers, as an antidote to Christianity.

At the end of the volume is an elaborate catalogue of the coins of Roman Manchester, prepared by Dr. R. S. Conway, assisted by Mr. McInnes and Mr. Brooke.

The supplemental volume describes some excavations made by the association on an earthwork at Toothill, in Macclesfield Forest. This earthwork has long puzzled antiquaries, and was generally believed before these excavations were made to be a Roman camp or fort. But not a single trace of Roman occupation was found, nor of pre-Roman; the work may have been mediæval, but no positive evidence of

way ultimately into recognised scientific or medical journals with fuller exposition and better illustrations.

The actual report of the committee occupies three pages out of a total of 134, the remainder being taken up by appendices. In the report the committee gives an account of its revenue, amounting to 3470*l.*, and the expenditure, totalling 3333*l.* 6*s.* 8*d.* The revenue is made up of contributions from the Imperial Government (1000*l.*), the Government of India (500*l.*), the Rhodes' Trustees (200*l.*), and Colonial Governments (1770*l.*); and, with regard to the last item, it is very satisfactory to learn that the Colonial Governments have one and all agreed to renew their grants for a further period of five years from 1909. The expenditure consisted of grants to the London School of Tropical Medicine (1383*l.* 6*s.* 8*d.*), the Liverpool School of Tropical Medicine (1000*l.*), the University of London (750*l.*), and the University of Cambridge (200*l.*). No grant was made to the Royal Society during the year, because the funds required for the continuation of the researches into sleeping sickness, carried on under the supervision of the society, were provided by the Uganda Protectorate.

The first appendix contains reports on measures taken for the prevention of malarial fever. A circular letter was dispatched by the Colonial Secretary to the Colonial Governors, enclosing (1) a letter from Sir William Osler, published in the *Times* of March 15, 1909, entitled "Malaria in Italy; a Lesson in Practical Hygiene," and (2) a report of the Bombay Medical Congress, published on March 16, 1909; and inquiring "to what extent the policy which Dr. Osler represents as having been so successful in Italy could be adopted in the territory under your administration." Replies are

printed from Ceylon, Mauritius, East Africa, Nyasaland, Somaliland, Uganda, Gambia, Gold Coast, Sierra Leone, Northern and Southern Nigeria, South Africa, Bahamas, British Guiana, British Honduras, Jamaica, Leeward Islands, Trinidad, Windward Islands, Australia, and Cyprus. These various replies furnish much interesting reading. In general the defence of dwellings and individuals against mosquitoes, the destruction, so far as possible, of the breeding-grounds of the mosquitoes, and the free distribution of quinine, are the measures most commonly adopted. The Acting Governor of the Leeward Islands reports favourably on the efficacy of the small fish known as "millions" (*Girardinus poecilioides*) in keeping down mosquitoes. The Governor of Nyasaland reports favourably on the success of anti-malarial measures in the townships and other European settlements, but is less hopeful with regard to the scattered native villages.

The remaining appendices consist of a report from Dr. H. G. Plimmer on his work on the experimental treatment of trypanosomiasis; reports from the professor of protozoology in the University of London, the Quick Laboratory, Cambridge, the London School of

Photo. by J. J. Phelps.

Samian Bowl found in Manchester in 1907. From "The Roman Fort at Manchester."

its age has yet been found. The rest of the volume describes the continuation of the work at the Roman Fort Melandra.

These volumes are well and clearly written, and very fully illustrated, and will be of the greatest value to students of Roman Britain.

ADMINISTRATION AND DISEASE.

THE report of the advisory committee for the Tropical Diseases Research Fund for 1909¹ contains so much original work that it should rank as a scientific publication. In it are to be found reports from all parts of the world in which the results of scientific investigations are communicated by those engaged in studies bearing directly or indirectly upon tropical diseases of all kinds. Some of these reports are even illustrated by figures, plain or coloured, which, however, for the most part, give the impression of either having been very badly drawn in the first place or very inadequately reproduced in this report. It is to be hoped that many of the important and interesting researches described here will find their

¹ Printed for His Majesty's Stationery Office, 1910. Cd. 4999 Price 2*s.* 8*d.*

Tropical Medicine, the Liverpool School of Tropical Medicine, and the various colonial laboratories; and, lastly, the circular letter sent by the Colonial Secretary to the Colonial Governors with regard to the renewal of contributions to the Tropical Diseases Research Fund. Many of these reports contain matter of much interest. From British Guiana come reports by the Government bacteriologist, Dr. K. S. Wise, and Prof. Deycke on the results of Prof. Deycke's treatment of leprosy during the first six months' trial. In the report of Dr. Castellani from Ceylon, peculiar parasites are described from the blood of man and other vertebrates in Ceylon, with illustrations of a relatively high standard. These parasites are found free in the blood-plasma and resemble the free "vermicules" of hæmogregarines, but do not appear to have any intracorporeal stage. Dr. Castellani considers them to be Protozoa of a genus distinct from hæmogregarines, and compares them with bodies found in human blood in Algeria by the brothers Sergent, whose name is translated into Sergeant, in our opinion somewhat unnecessarily.

From East Africa the Government bacteriologist, Dr. P. H. Ross, gives an account of a number of experiments on the transmission of trypanosomes by *Glossina fusca* and *G. longipennis*. Amongst these special interest attaches to one in which a monkey was successfully infected with *Trypanosoma gambiense* by means of *Glossina fusca*, by the method of interrupted feeding. Two flies were used in this way on October 5, being first fed on an infected monkey and then transferred immediately to a healthy monkey; the experiment was repeated with three more flies on October 8; trypanosomes were first found in the blood of the second monkey on October 31. These experiments tend to show that tsetse-flies of species other than *G. palpalis* can transmit sleeping sickness by the direct or purely mechanical method.

The report shows the value and importance of the researches on tropical diseases that are being carried on in all parts of the world under the auspices of the Colonial Office and the Colonial Governments. Not only is the report encouraging for the future, but it is most interesting and instructive reading, and well worth the modest sum for which it is sold.

NOTES.

SIR ARCHIBALD GEIKIE, K.C.B., P.R.S., has been elected a foreign member of the Royal Danish Society of Sciences, Copenhagen.

The death is announced, at eighty-four years of age, of Prof. Julius Kuehn, for many years professor of agriculture in Halle University.

The annual meeting of the Iron and Steel Institute will be held on Wednesday and Thursday, May 4 and 5. On May 4 the retiring president (Sir Hugh Bell, Bart.) will induct into the chair the president-elect (the Duke of Devonshire). The Bessemer gold medal for 1910 will be presented to Mr. E. H. Saniter, and the president will deliver his inaugural address. A number of important papers will be read and discussed during both days of the meeting.

The Geneva correspondent of the *Daily Chronicle* states that a monument in memory of Prof. Tyndall will be erected on the summit of the Bel Alp, 6735 feet high, a little above the place where for many years Tyndall resided during the summer months. Mrs. Tyndall has engaged M. F. Correvon, of Geneva, to design the monument, which is a large conical block of granite. It will be erected by the Swiss Alpine Club in July on Bel Alp, overlooking the Aletsch Glacier.

THE executive committee of the National Physical Laboratory has appointed Mr. J. E. Sears to take charge of the work of the metrology division of the laboratory in the place of Mr. H. Homan Jeffcott, who has been nominated recently to the professorship of engineering in the Royal College of Science, Dublin. Mr. Sears, who was formerly at St. John's College, Cambridge, graduated with first-class honours in mathematics and engineering, and is an associate member of the Institution of Civil Engineers.

UNDER the title of the *Journal of Genetics*, it is proposed to publish a periodical for original research in heredity, variation, and allied subjects. The journal will also, from time to time, contain articles summarising the existing state of knowledge in the various branches of genetics, but reviews and abstracts of work published elsewhere will, as a rule, not be included. Adequate illustrations will be provided, and, where the subject-matter demands it, free use will be made of coloured plates. The journal will be edited by Prof. W. Bateson, F.R.S., director of the John Innes Agricultural Institution, and Prof. R. C. Punnett, professor of biology in the University of Cambridge, and it will be published by the Cambridge University Press. It is hoped that the first number will be ready in August.

ON Tuesday next, April 26, Prof. F. W. Mott will begin a course of three lectures at the Royal Institution on "The Mechanism of the Human Voice"; on Thursday, April 28, Mr. W. McClintock will deliver the first of three lectures on "Blackfeet Indians in North America"; and on Saturday, April 30, Dr. D. H. Scott will commence a course of three lectures on "The World of Plants before the Appearance of Flowers." The Friday evening discourse on April 29 will be delivered by Dr. Tempest Anderson on "Matavau: a New Volcano in Savaii (German Samoa)"; on May 6 by Sir Almroth Wright, on "Autoinoculation"; and on May 13 by Prof. W. H. Bragg, on "Radio-activity as a Kinetic Theory of a Fourth State of Matter."

AN interesting light has just been shed upon a controversy which excited some attention in 1907 (see *NATURE* of that year, September 26, p. 545, and October 17, p. 615) by the publication of the official report on "The Tomb of Queen Tiya" (Constable and Co., Ltd., 1910). Two years ago archæologists maintained that the bones found in the tomb were the remains of the mummy of the queen herself, and seemed to regard as a matter of little importance the anatomical fact that the skeleton was that of a young man. Sir Gaston Maspero now states (*op. cit.*, p. i) that "when we came to examine the mosaic coffin and the sheets of gold in which the mummy was wrapped, we found that their legends asserted the mummy to be no other than Khuniatonu himself" (Queen Tiya's son).

THE Seismological Society of America at a recent meeting passed a series of resolutions expressing its views on the establishment of a National Bureau of Seismology, and decided that copies of the resolutions should be transmitted to the President, President of the Senate, the Speaker of the House of Representatives, and the secretary of the Smithsonian Institution. After enumerating the chief earthquake disasters in the United States, and summarising what has been done in other countries for the encouragement of the study of seismology, the resolutions state that the Seismological Society of America strongly favours the establishment of a National Bureau of Seismology with power (a) to collect seismological data; (b) to establish observing stations; (c) to study and

investigate special earthquake regions within the national domain; (d) to cooperate with other scientific bodies and organisations and individual men of science in forwarding the development and dissemination of seismological knowledge. The society also favours the organisation of this bureau under the Smithsonian Institution, with the active cooperation of other scientific departments of the Government.

In the death of Sir Walter Palmer, Bart., on April 16, at fifty-two years of age, the cause of higher education has suffered a heavy loss. Nowhere will that loss be felt more grievously than at Reading, for to Sir Walter Palmer more than perhaps to any other individual the University College of that town owes its origin and rapid development. Largely to his initiative was due the merging, some twenty years ago, of the University Extension Centre and the School of Science and Art into one institution, which has become the flourishing University College of to-day. The number of the benefactors of higher education in this country is not large. The institutions which they aid make heavy claims upon them, claims, not only on their wealth, but also on their time. That these claims are met unflinchingly by men like Sir Walter must rejoice the hearts of those who believe that, "after bread, education is the first need of a people." From 1897 to 1903 Sir Walter was chairman of council, and in that capacity received the Prince of Wales on the occasion of the opening of the new college buildings in 1898. After his resignation of the chairmanship he remained a member of council and of the academic board. His deep and abiding interest in education was not confined to Reading; and the work done by him in London—he was a member of the Senate of the University of London—is widely known and appreciated.

THE Liverpool Marine Biological Station at Port Erin has been very fully occupied with workers during the present spring vacation. In the month from the middle of March more than forty senior students and professional biologists, representing six or seven universities, have occupied work-places. Amongst these may be mentioned Mr. Walter Tattersall (development of *Littorina*), Dr. Henderson (development of plaice), and two senior students, all from the University of Manchester; Dr. Stuart Thomson (*Alcyonaria*), from Bristol University; Mr. W. J. Dakin (memoir on *Buccinum*), from Belfast University; Mr. W. Riddell (plankton), Dr. J. Pearson (memoir on skate), Mr. Douglas Laurie, Prof. Herdman (plankton), and about twenty-five senior students from the biological departments of Liverpool University; Prof. Cole and three senior students from Reading; two from Cambridge, one from Birmingham, and a few others. Every work-place is now occupied, and an extension of the laboratory accommodation is urgently required. Work at sea, from the *S.Y. Ladybird*, is being carried on actively. The plankton on the surface of the Irish Sea is at present very abundant, and all the nets are giving large hauls. The vernal increase in phyto-plankton (such as diatoms) made its appearance this year between March 22 and 26, an unusually early date. Last year the phyto-plankton was not present in quantity (more than a million per fifteen minutes' haul of standard net) until April 19; in 1908 it began about the middle of April (from April 13 onwards), and in 1907 the maximum covered the last week of March and first fortnight of April—apparently the present season is more like 1907 in this respect than the two intermediate years. In the fish-hatchery the present season has been a late one, but in other respects is satisfactory. The spawning of the parent plaice (about

400 adult fish) in the pond began on February 14, but the numbers of fertilised eggs produced remained low until March 7, since when they have been spawned in abundance, the maximum on one day being 634,000, on April 12. The total number of eggs skimmed from the pond, to April 16 inclusive, is above 8½ millions, and the number of larval plaice set free in the open sea, to April 15, is 3,365,000. The spawning is still in progress, and will probably continue for several weeks.

DR. KNUT STJERNA, a promising anthropologist of Upsal, whose death, we regret to learn, occurred at an early age in November last, contributed to the January-February number of *L'Anthropologie* an elaborate paper entitled "Les Groupes de Civilisation en Scandinavie à l'Epoque des Sépultures à Galerie." He recognises the remains of three races in this region:—first, the east and north were occupied by a race of fishermen and hunters, who retained much of the Palæolithic culture, and were connected across the Aland Archipelago with the people of east and south-east Europe; secondly, the Danish islands and the adjoining mainland were colonised by a people skilled in bee-culture, who possessed a regular type of weapons, and traded in the North Sea; lastly, there was on the west a foreign race, emigrants from Central Europe, possessing a civilisation which at the close of the period of the gallery tombs had begun to assert its influence on the adjoining Scandinavian races.

THE question of the origin and distribution of the cross-bow in India presents an interesting problem. Mr. G. Forrest, in the *National Geographic Magazine* for February, under the title of "The Land of the Cross-bow," describes its use by a people whom he calls the "Lissoos" in the Upper Salwin valley in Burma. The bow is made of wild mulberry, with a span of 5 feet and a pull of 35 lb.; the stock is of wild plum wood, the string of plaited hemp, and the trigger of bone; the arrows are made of split bamboo, 16 or 18 inches long, and poisoned with aconite. Sir J. G. Scott describes a similar weapon in use among the Lashis or Yawwins and the Kachins. It is not mentioned by Messrs. Skeat and Blagden as in use among the Pagan races of the Malay Peninsula. Mr. Thurston, in his recent work on the "Castes and Tribes of South India," says that he found a weapon of this type in use among the Ulládans, a wild tribe of Travancore, for shooting fish, and a specimen of the weapon, now in the Pitt Rivers Museum, Oxford, was picked up among the Korwas, a wild tribe in Central India, south of the river Son. The Ulládans seem to speak of it as the Firingi (Frank or European) weapon, but it is difficult to suggest any route by which it could have reached the Burmese tribes. Being an obvious development of the common bow, it may have been independently invented by them.

At the end of an account of the birds obtained during the Alexander expedition to Alaska in 1908, Dr. J. Grinnell, in vol. v., No. 12, of the University of California Zoological Publications, directs attention to the tendency to melanism among the avifauna of the district. In this respect Alaskan birds resemble those from other regions with a heavy rainfall and damp climate. The melanism, there and elsewhere, cannot be directly attributed to the heavy precipitation, nor, in the author's opinion, to the humidity and paucity of light, but the true cause of the phenomenon is not at present apparent.

WE have to acknowledge the receipt of the volume of the *Sitzungsberichte der k. Bohm. Ges. der Wissenschaften* for 1909, and among the contents we may refer

to an account by Dr. Anton Fritsch of the discovery in the granitic area of Skuč of a superjacent deposit of altered sandstone containing Rudistæ and a number of other Upper Cretaceous molluscs. Another remarkable geological discovery recorded, by Mr. A. Hofmann, in the same volume relates to the occurrence of rounded pebbles of quartzite and other rocks in the brown coal formation. The author figures specimens of these pebbles *in situ*, but reserves an explanation of their mode of occurrence.

ZOOLOGICAL serials, both English and American, are flooded with descriptions of new forms of mammals from British East Africa, the American descriptions being based on specimens obtained during the Roosevelt expedition, which appears to have induced English naturalists to overhaul the collections in this country. The chief American contributors are Messrs. Heller, Miller, and Osgood; and among a batch of papers recently received we may refer to one by Mr. Heller on a sable antelope from the Shimba Hills, which is described as a new species, although, as it differs from the typical *Hippotragus niger* mainly by the non-assumption of the full sable livery, it is better regarded as a race of that species. A similar remark is applicable in the case of several of the other new forms, which are mostly rodents, and to the Angolan hippopotamus described by Mr. Miller as *Hippopotamus constrictus*.

IN the *Zoologischer Anzeiger* of March 1 (vol. xxxv., pp. 500-8) Dr. Max Schlosser announces the discovery in the Fayum Oligocene of remains of Primates which are referred to three new genera, viz. *Mœripithecus*, *Parapithecus*, and *Propithecus*. The last, as represented by *P. haeckeli*, is a small ape intermediate in size between *Chrysothrix* and *Cebus*, with the normal simian lower dental formula, the canine and premolars being vertical, and the two branches of the lower jaw running nearly parallel and forming a firm symphysis. Phylogenetically, this genus is regarded by its describer as of high importance, since, in his opinion, it is the ancestor, not only of the Simiidae, but also of the Hominidae. *Parapithecus fraasi* is a small species of the size of a squirrel-monkey, with the lower dental formula i.1, c.1, p.3, m.3. It is regarded as connecting the Eocene Anapomorphidae with the Simiidae, and perhaps also with the Cercopithecidae. *Mœripithecus markgrafi* is too imperfectly known to admit of its systematic position being determined; it was about the size of a spider-monkey. Dr. Schlosser also describes a number of new types of hyracoids from the Fayum, among which *Bunohyrax* is based on some of the species included by Dr. Andrews in *Geniohyus*, both genera being regarded as bunodont hyracoids. In this connection it may be mentioned that Dr. Marcellin Boule (*Comptes rendus*, vol. cl., p. 812) has just described remains of a species of the Siwalik genus *Merycopotamus* from Upper Tertiary strata in southern Tunisia. This *M. africanus*, as it is named, affords further evidence in favour of Dr. Arldt's theory as to the migration of the Siwalik fauna through a forest-tract to Africa.

THE association of particular species of insects with particular flowers has always been a matter of interest to those who concern themselves with the question of the natural means of cross-fertilisation by insect agency. With respect to our native orchid, *O. maculata*, previous records have generally credited insects other than Lepidoptera as being the fertilising agents. In the *Entomologist* for November, 1909 (vol. xlii., p. 281), Prof. Meldola recorded the capture in August at Onich, Inverness-shire,

of a specimen of the common "shark," *Cucullia umbratica*, with one of the pollinia of *O. maculata* attached to its head, thus proving that this moth visits the flower in question. Prof. Meldola's observation has been followed up by Mr. A. M. Stewart, of Paisley, who in the current number of the *Entomologist* (April, vol. xliii., p. 106) records *Plusia festucae* as a fertiliser of the same orchid. In view of the large numbers of moth collectors now at work in this country, it is remarkable that such few observations of this kind have been placed upon record. Photographic reproductions of the heads of both species showing the pollinium *in situ* are given in the *Entomologist* for this month.

WE have received the Year-book for 1909 of the Dairy Students' Union, a body founded four years ago to assist its members with advice on various difficulties that arise and information of vacancies occurring in different branches of dairying, and "to create and stimulate interest in scientific research and new inventions in the dairy world." The book contains several short articles by Messrs. Blackshaw, D. A. Gilchrist, T. R. Robinson, C. W. Walker-Tisdale, and other dairy writers, and there is an interesting set of replies to queries that have been sent in by members during the year and dealt with by the advisory board.

THE direct determination of the total solids in milk presents certain practical difficulties which would be of serious disadvantage to the ordinary analyst who has to make a large number of determinations. It is found, however, that a simple formula expresses with sufficient accuracy the relation between the total solids, the fat (as determined by Gerber's or similar methods), and the specific gravity determined by the lactometer. Mr. Collins has recently issued an account of a slide rule that he has invented, and is now on the market, by which the necessary calculation, including the temperature correction, may be made at one setting. Such a rule will be of great benefit to the busy milk analyst, who has hitherto had to work out the calculation in the ordinary way. The paper is published in the University of Durham Philosophical Society's Proceedings.

PRINCE GALITZIN has recently published an interesting study of the records of the great earthquake of January 22 (*Bull. de l'Acad. Imp. des Sci. de St. Pétersbourg*, 1910, pp. 211-6). He estimates the distance of the epicentre from Pulkowa at 2400 km., and its azimuth N.W. -49.4° . From these data he assigns the following position for the epicentre, lat. 68° N., long. 17° W., that is, a little to the north of Iceland. This agrees somewhat closely with the position calculated by Dr. Tams from the epicentral distances from Jugenheim, Strassburg, Vienna, and Hamburg, namely, lat. $70.3^\circ \pm 1.7^\circ$ N., long. $14.3^\circ \pm 2.2^\circ$ W. According to intelligence received from Iceland, a violent earthquake took place in the neighbourhood of that island about the time mentioned.

THROUGH the courtesy of Dr. Reusch, director of the Geological Survey of Norway, we have received an abstract of the history and proceedings of the Norsk Geologisk Forening, founded in 1905, and of its predecessor, the Geologisk Klub of Christiania. This history is reprinted from the journal of the society, the *Norsk Geologisk Tidsskrift* (Bind i., 1909), and forms a complete record of investigations and discussions since 1893. Like the old Geological Club in London, the Norwegian club consisted mainly of men engaged in active geological research, and this character is maintained by its successor, the forty members of which resemble an academy rather than a general geological society. In the first volume of the *Tidsskrift* some of the papers are in German, while

others have summaries in English. Scandinavian geology, as is well recognised, has a special interest for workers on our pre-Devonian rocks and for all interested in recent modifications of our shore-lines.

THE first part has appeared of the comprehensive work entitled "Handbuch der Regionalen Geologie," edited by Profs. Steinmann and Wilckens, of Bonn (Heidelberg: Carl Winter, 1910). This includes the whole of Denmark, by Dr. N. V. Ussing, of Copenhagen, and is published at the moderate price of 1.60 marks, or 1.20 marks to subscribers. The scheme of the editors is already in full operation, and some sixty contributors of various nationalities are at work on the subdivisions of the eight royal octavo volumes. Landscape illustrations are excluded, but sketch-maps and sections are given in the text. The references to original memoirs are likely to be especially useful. The present part of 38 pages, so convenient to carry in the hand-bag, will form a companion for all scientific visitors to Denmark. One of the maps shows how the post-Glacial uplift of Scandinavia has affected a large part of the Danish peninsula and the islands. Bornholm falls into the Scandinavian region, and contains rocks from the pre-Cambrian up to the Liassic systems, unknown otherwise in Denmark. Attention is directed to the Middle and Upper Jurassic and Lower Cretaceous strata of Jutland, represented only by boulders in the drift. The various oscillatory movements that have given the kingdom its present outlines are well stated on p. 26.

A PRELIMINARY report on the mineral production of Canada during the year 1909 has been prepared by Mr. John McLeish, chief of the Division of Mineral Resources and Statistics, and published by the Mines branch of the Canada Department of Mines. The total value of the mineral production during the year was upwards of 18,000,000., an increase of 5 per cent. over 1908. Of this total, 49.9 per cent. represents metals, 49.7 per cent. non-metallic products, the remaining 0.4 per cent. being mineral products not reported. Coal is still the most important Canadian mineral, and constitutes 27 per cent. of the total. Silver occupies second place with 15.9 per cent., gold and nickel come next with 10.8 and 10.5 per cent. respectively, and copper contributes 7.8 per cent. The metals nearly all showed an increased output compared with 1908, while in the non-metallic class there is a larger number of products showing increases than those showing decreases. The increases were very noticeable in the cases of corundum, gypsum, natural gas, salt, and in the structural materials, cement, clay products, lime, and stone.

IN a paper published in Petermann's *Mitteilungen* Dr. Marquardsen, of Göttingen, reviews the present state of our knowledge of the topography and hydrography of the inland drainage area of the Sudan and Sahara. The total area of this region is estimated at 2,139,000 square kilometres. Dr. Marquardsen states some interesting results with regard to Lake Chad; the variations in size and level do not, in his opinion, indicate a progressive change in climate since its discovery by Denham in 1823; the lake appears to be shifting northward and gradually filling up. The question of the ultimate filling up of the whole basin, and breaking through of the streams which now supply Lake Chad, is discussed; and in this connection special significance is attached to the Logone-Tuburi bifurcation and the activity of the source streams of the Benue.

THE climatology of 1909, as recorded at the Juvisy Observatory, is reviewed by MM. Flammarion and J. Loisel in No. 2 (1910) of the *Bulletin de la Société astronomique de France*. The form of the discussion and

of the comprehensive set of curves follows that of previous years, each element in the climatological record being discussed separately and compared with the same element in former seasons and years. Thus we see that 1909 was one of the coldest years since 1885, the mean temperature for the year (9.5° C.) being the lowest since 1891; in the matter of mean summer (June, July, August) temperature the value (16° C.) was the lowest since 1886, when the records were commenced. Similarly interesting comparisons are made for the other elements.

MESSRS. GEO. PHILIP AND SON have sent us a cardboard model, designed by Mr. Rupert Hicks, to show the relative positions of Halley's comet, the sun, and the earth during the present apparition. The model consists of a piece of stout cardboard 12 inches by 10 inches, near the centre of which is fixed a gilded disc representing the sun. Attached by an arm to the latter is a circle representing the earth, the revolution being provided for by the sun being pivoted at the centre. Then on a longer arm is affixed a model comet, which may describe an arc representing that part of the comet's path lying within the orbit of the earth. Thus one gets the comet's path, relative to earth and sun, from March 10 to May 30, and, by swinging the discs into their appropriate positions on the dated arcs, it is possible to see at a glance the conditions governing the visibility of the comet and its tail on any specified date; the tail is made long enough to illustrate the probable passage of the earth through it on May 19. The price of the model is 1s. net, post free 1s. 1d., and as a method of illustrating to non-astronomical people the various conditions under which the comet appears and disappears the model should prove instructive and interesting.

THE February number of the *Journal of the Institution of Electrical Engineers* contains a communication made to the Manchester section of the institution by Mr. J. W. Warr on the electric ignition of internal-combustion engines. Descriptions of the principal methods of electric ignition at present in use are given, but the author expresses a decided preference for the high-tension method both for stationary engines and for motor-cars. The simplicity of the means of production of the current for low-tension methods is more than compensated by the trouble introduced by the mechanical contact breakers which are then necessary to produce the spark. Of the various high-tension methods, Mr. Warr considers that depending directly on a magneto machine to be the most trustworthy.

ACCORDING to an article in the February number of *Le Radium*, M. T. Bialobjeski has commenced at the Collège de France an examination of the effects of the β and γ rays of radium on the conductivity of solid dielectrics. His method is to use the dielectric in a condenser the plates of which are horizontal, the lower one being connected through an electrometer to earth, while the upper one consists of a thin sheet of aluminium foil kept in contact with the dielectric by means of a ring of lead. The rays from 1 milligram of radium bromide contained in a platinum capsule closed by a mica window fall on the upper plate of the condenser and pass through it to the dielectric beneath. The potential difference between the plates is maintained by storage cells, and can be increased to 1800 volts. The current produced is measured by the rate of motion of the electrometer needle. Sulphur, paraffin, wax, and amber have up to the present been examined. For discs more than 1 millimetre thick the current was proportional to the electromotive force used.

For smaller thicknesses the behaviour varied greatly with the material, but the author hopes to explain the whole of the phenomena observed by means of the ionisation theory.

THE launch of H.M.S. *Colossus* was carried out successfully on Saturday, April 9. This vessel has been constructed by Scott's Shipbuilding and Engineering Company, of Greenock. That the work has been carried out expeditiously will be evident from the fact that the keel was laid less than nine months ago. The ship will have a displacement of 20,250 tons, and has a length of 510 feet, beam 86 feet, and a designed speed of 21 knots. Parsons turbines and Babcock boilers of 25,000 horse-power will be fitted, and good progress has been made with these also. The launching weight was 7500 tons, and the vessel was completely afloat 58½ seconds after the first movement, which occurred without the vessel hanging on the ways for any appreciable time.

An interesting article on the development of the hydraulic reaction turbine in America, by H. Birchard Taylor, appears in the *Engineering Magazine* for March. American makers have advanced greatly since 1890, and have abandoned the methods of "trial and error" in vogue prior to that date, methods which caused the Niagara Falls Power Company to go abroad for the designs of their first machines. To-day, American designers are in a position to design and construct machinery to meet the most severe requirements, and have to their credit the largest turbines in the world, among which may be mentioned the four 13,000-horse-power Francis turbines, now operating in the plant of the Toronto Power Company at Niagara Falls. The author of the article has given special attention to erosion, and brings forward evidence which indicates that trouble owing to this cause may be eliminated by correct design. Thus a bronze wheel under a head of 266 feet was so eroded at the end of a few months that it was necessary to replace it. A new wheel, of slightly different design, but of precisely the same material, ran five years without showing any signs of wear. Electrolysis and chemical action are considered by Mr. Taylor, who believes that both can be eliminated by properly designing the wheel blades.

THE issues of *Engineering* for April 8 and 15 contain a detailed account of some experiments upon the flow of water over triangular notches, carried out by Mr. James Barr at the James Watt Engineering Laboratories at Glasgow University, under the supervision of Prof. Archibald Barr. The late Prof. James Thomson first investigated this form of notch in 1860 and 1861 with rather crude apparatus. It speaks well for his skill as an experimenter that the present series, with elaborate and finely constructed apparatus, show no divergence from Thomson's conclusions. Thomson's law, that the quantity flowing is, in almost all cases, proportional to the $5/2$ power of the head, has been verified. Further investigation shows that the prevention of the inward flow of the water at the sides of the notch, whether caused by the narrowness of the channel of approach or by the roughness of the upstream surface of the notch, produces an increase in the quantity flowing over the notch. Various notches were experimented upon, the value of the coefficient in Thomson's formula for a narrow surface, right-angled notch being found to vary from 0.3104 at a head of 2 inches to 0.2995 at a head of 10 inches. Thomson's average value of 0.305 for heads from 2 to 7 inches must have been very near the truth. The articles are well illustrated, and give full tables and curves of results.

MESSRS. CONSTABLE AND Co. are publishing immediately a little book of pocket size, being a "Guide to the Preservation of Health in West Africa," by Mr. Henry Strachan, principal medical officer in southern Nigeria. They announce also the forthcoming publication of a series of essays dealing with the consideration of the introduction of an international language into science. Such a language has been constructed by an international commission, and the English edition of the essays in which it is presented is by Prof. F. G. Donnan.

MESSRS. W. WESLEY AND SON, Essex Street, Strand, London, W.C., have just issued a classified catalogue of manuscripts, books, and pamphlets on astronomy, including the libraries of the late Miss A. M. Clerke, Dr. A. A. Common, Mr. E. Crossley, and Captain W. Noble. The catalogue includes the titles of about 3700 works, arranged in alphabetical order, according to authors' names, in groups relating to the various branches of theoretical and practical astronomy and astronomical physics. The classification renders it easy to find the works which Messrs. Wesley have available upon any particular subject of astronomical study or research, and all who are desirous of filling up gaps in their libraries should see this catalogue.

OUR ASTRONOMICAL COLUMN.

OBSERVATIONS OF COMETS.—In No. 4402 of the *Astronomische Nachrichten* Dr. Wolf directs attention to a peculiarity in the form of comet 1910a. Besides the main and subsidiary tails, Dr. Wolf's photographs show a conical faint mass of material extending from the base of the coma towards the sun, quite different from anything he has seen in previous comets, and having the appearance of a miniature zodiacal light. The point of the cone was in position-angle 215° , 180° from the direction of the axis of the tail, and was at a distance of $13'$ from the nucleus.

Comet 1909e (Daniel) was photographed at Heidelberg on February 28, and Dr. Wolf also publishes the latest-determined position of comet 1909a, determined from a photograph secured on August 19, 1909, when the comet was fainter than the sixteenth magnitude.

Observations published by Dr. Graff in the same journal show that during January comet 1909e was a large nebulous mass, $3'$ in diameter, with a nucleus of magnitude 12.5.

OBJECTIVE-PRISM DETERMINATIONS OF RADIAL VELOCITIES.—An ingenious method of determining, approximately, the approach or recession of faint stars is proposed by Prof. Pickering in Circular 154 of the Harvard College Observatory. Various methods have been proposed before, but have not proved remarkably successful. In one of these it was proposed to introduce a standard artificial absorption band in the spectrum of each star, but the didymium and hyponitric acid filter then employed produced bands which were far too wide and hazy for precise measurement.

This difficulty has now been largely removed by Prof. R. W. Wood, who has devised a filter giving an absorption band at λ 4272 which is distinctly more definite than the hydrogen lines in first-type stars. The filter is a weak solution of neodymium chloride, and further experiments are in progress to reduce the thickness of the absorption band by the addition of lanthanum and phosphoric acid. Trial exposures have shown that for ninth-magnitude first-type stars the probable error, at present, is about 10 km., and for eighth-magnitude second-type stars somewhat less; a number of reproductions of the photographs obtained accompany the circular.

Prof. Pickering also enumerates the available objective-prism equipment at Harvard, and states that they are ready to take such photographs as may be desired; further, he invites cooperation from astronomers experienced in radial-velocity work.

ENCKE'S COMET, 1895-1908.—The Monthly Notices for March (vol. lxx., No. 5, p. 429) contains a discussion by Dr. Backlund of the motion, brightness, &c., of Encke's comet during the period 1895-1908. In the first place, he deduces elements fitting the observations of 1895, 1901, and 1904, and shows that the acceleration of the mean motion was not constant during the period under discussion. This leads to a discussion of the various causes which might produce the diminution observed, and of the probable time at which such causes, or cause, were, or was, effective. Excluding solar electrical forces, it seems probable that the resistance encountered is a meteoric swarm in the neighbourhood of perihelion, and the decrease of the acceleration must be attributed rather to the diminution of the density of the resisting medium than to changes in the comet itself. If, however, the variation of the acceleration is held to be actually connected with the maxima of solar activity, tangential electrical forces are admissible in explaining it, and the problem becomes indeterminate.

Various causes of the comet's fluctuations in brightness, e.g. an alteration in shape, and therefore in surface presented, produced by the solar tidal action, are discussed, but no explanation is entirely satisfactory, and the question is left open.

Dr. Backlund then investigates the relation between Wolf's comet of 1907 and Encke's comet, and the possibility of capture by Jupiter. Whilst not proving that the comet was captured, he shows the possibility of such capture having taken place within the past 5700 years.

THE SPECTRA OF THE MAJOR PLANETS.—In Bulletin No. 42 of the Lowell Observatory Dr. V. M. Slipher publishes further descriptions and reproductions of the spectra of the major planets. The photographs were taken with plates especially sensitised for the red end of the spectrum, and show a wealth of detail between D and A. Comparative exposures on the south equatorial dark belt and the bright equatorial region of Jupiter indicate no reason for supposing that the darker portions of the planet are those lying the deeper. The spectrum of Saturn is generally similar to that of Jupiter, but there is a strong band in the latter at λ 646 which is absent, or nearly so, in the former; as the others are of the same intensity, this points to the existence of a constituent in Jupiter's atmosphere which is absent in that of Saturn. No trace of the planetary bands is found in the spectra of Saturn's rings, and there is no indication of any atmosphere about the rings.

A comparison of the spectra of the four major planets shows that in Neptune all the bands seen in the other three are intensified, except that at λ 646, which appears to be peculiar to Jupiter. The evidence for hydrogen absorption in the atmospheres of Uranus and Neptune is very slight, and the intensification of C and F is not copied by the hydrogen bands at $\lambda\lambda$ 4341 and 4102, so far as an ordinary eye examination can determine, so that, at the best, the identity can only be considered probable. Of the other bands photographed scarcely anything is known, but it is shown that the very strong band at λ 619 is not identical with one in the spectra of red stars, as is sometimes stated.

THE INTRINSIC BRILLIANCY OF THE SUN.—In a previous paper Dr. Nordmann estimated that the intrinsic brilliancy of the sun was 319,000 decimal candles per sq. cm. (NATURE, March 3, p. 29), but he now finds that one of his data, owing to an ambiguity in Müller's text, is incorrect. He has, therefore, re-calculated his value, and gives, in No. 13 of the *Comptes rendus* (March 29), 100,500 decimal candles per sq. cm.

THE CARNEGIE INSTITUTION OF WASHINGTON.

THE eighth annual report of the Carnegie Institution of Washington, describing the work of the institution during the year 1909, has now been published. It is a well-illustrated volume of 259 pages, dealing with the work of administration, the investigations carried out under the auspices of the institution, the various publications, the expenditure recommended for 1910, and additional sugges-

tions. Subjoined are extracts from the report of the president of the institution upon the progress of the different scientific departments.

Among the more important events of the year are the completion of the administration building in Washington, the establishment and active operation of the observatory of the department of meridian astrometry in Argentina, the construction and putting into commission of the non-magnetic ship *Carnegie* of the department of terrestrial magnetism, and the inauguration of the project for the publication of an edition of the master-works on international law. Attention is directed to the fact that with these, and with the previously established larger enterprises under way, the accumulated income of the institution has been exhausted, and that there will be no room for further expansion under current income in the immediate future.

In the last annual report a summary statement of the work of the institution up to October 31, 1908, was given. A more detailed study of the scope and geographical range of this work shows that investigations have been carried on under the auspices of the institution in more than thirty different fields of research, and that these investigations have extended to more than forty different countries. The total number of volumes of publications issued directly by the institution is 141, with an aggregate of about 35,000 pages of printed matter. For the larger departments of investigation there are now provided two astronomical observatories, five laboratories, and one ship. A complete list of the equipments of these establishments includes fifty-eight buildings and eight smaller craft in addition to the ship *Carnegie*. The total amount of funds granted for expenditure is \$64,000. The total amount expended is \$25,900.

At the date of the preceding annual report the department of meridian astrometry was engaged in the construction of a temporary observatory at San Luis, Argentina. The instrumental equipment for this was shipped from the Dudley Observatory, Albany, N.Y., in December, 1908. After safe transportation to San Luis, the constants of the meridian transit, the principal instrument used, were carefully re-determined, proving to the highest order of precision that this instrument suffered no injury in transshipment. With this indispensable preliminary investigation completed, the work of stellar observation was begun in April, 1909, and is now going on at a rapid rate.

The following list shows the departments of investigation to which the larger grants were made by the trustees and the amounts allotted from those grants by the executive committee during the year:—

	£
Department of Botanical Research ...	6,400
Department of Economics and Sociology ...	3,500
Department of Experimental Evolution ...	5,800
Department of Historical Research ...	4,100
Department of Marine Biology ...	3,000
Department of Meridian Astrometry ...	6,000
Department of Terrestrial Magnetism ...	12,000
Department of Terrestrial Magnetism, vessel ...	15,000
Geophysical Laboratory ...	9,000
Horticultural work of Luther Burbank ...	2,000
Nutrition Laboratory ...	5,000
Solar Observatory ...	20,800
Division of Publications ...	900

The various investigations of the botanical research department have been successfully continued during the past year. Among these, the experiments of the director in the production of mutants in plants seem destined to play a fundamental rôle in the determination of the absorbing biological question of the derivation of species. Equally important in this same line are the experiments with beetles of Prof. Tower, for which vivaria are now maintained at the Desert Laboratory at Tucson and at the Marine Biological Laboratory at Dry Tortugas, Florida.

The work of the department of experimental evolution presents a double interest in furnishing evidences at once of the evolution of organic forms and of the evolution of a science. The history of biological science, like the history of most sciences in their earlier stages, has been and still is, marred to some extent by heated controversy. But all this is destined to disappear with the rise of biology.

to the plane of quantitative determination. It is on this plane that the department in question is seeking, with capital initial success, to carry on its investigations. The publications of the department already issued are reckoned among the most important of recent contributions in this large field of research.

The work of the geophysical laboratory proceeds by means of some of the most recent methods and appliances of research, and hence its aims and lines of investigation, like those of all new sciences, present to the public more or less of obscurities of interpretation and obstacles to ready appreciation. The researches of the laboratory afford another instance of the normal evolution of a science from the observational and descriptive stage to the higher level of measurement and calculation. That geology and mineralogy will be much advanced by such researches is now recognised and attested by eminent specialists. Indeed, the definitive results already attained by members of the laboratory staff are now finding their way into the elementary as well as into the more technical literature of those sciences. The equipment of the laboratory has received an important addition during the year in apparatus for subjecting materials under observation to high pressures and temperatures, either simultaneously or separately. This apparatus, developed by Dr. A. Ludwig, research associate of the department for the year, will give pressures up to 17,000 atmospheres, or 250,000 lb. per square inch.

The Tortugas laboratory of the department of marine biology is proving highly effective as a centre for research by a wide range of specialists. Eight associate investigators have availed themselves of the opportunities afforded by the department during the past season, and the results of their studies are now in preparation for publication as contributions to science from the laboratory. It is of interest to note the advent of quantitative investigations here as well as elsewhere in the advancing biological sciences.

The apparatus of the nutrition laboratory proves highly effective, and the experiments already made, on pathological as well as normal subjects, fully justify the confident expectations hitherto entertained with respect to this line of research. Many additions have been made during the year to the equipment of the laboratory. Among these are a bed-calorimeter into which a recumbent patient may enter with ease and safety; a portable respiration apparatus which may be applied readily to a patient reclining on a cot while his respiratory action is accurately determined; and an automatic temperature register, which will give a continuous record of temperature changes in the calorimeters to which it is applied.

The achievements already attained in the development of novel methods and effective apparatus for studies of the sun, and the additions to our knowledge of solar physics already made at the solar observatory, not only justify the predictions of its founders, but warrant the anticipation of still more important contributions to astrophysics in the near future. Work of investigation and work of construction have proceeded simultaneously during the year, both at the observatory site on Mount Wilson and at the shops and physical laboratory in Pasadena. The 60-inch equatorial reflecting telescope, the installation of which was completed a year ago, has been tested during the past year and proved to be of unequalled excellence, whether used as a visual or as a photographic instrument. Its optical perfection and its wide range of applicability make it a noteworthy contribution to progress in observational astronomy. The 150-foot tower telescope, authorised by the budget of the current year, is in a forward state of construction, and will soon become one of the most effective units in the telescope battery of the observatory. The discovery of the existence of the Zeeman effect in the sun, announced by the director a year and a half ago, has been confirmed and extended in its application to further interpretation of the nature of sun-spots, as well as to researches into the more recondite electromagnetic properties shown by the sun. Closely connected, apparently, with these properties are the major and minor "magnetic storms" to which the earth's magnetism is subject, now of special interest alike to the staff of the solar observatory and to the staff of the department of terrestrial magnetism. It may suffice here to record only one other item of interest, namely, the failure, thus far, of

the manufacturers of glass at St. Gobain, France, to furnish a satisfactory disc for the 100-inch Hooker telescope. The disc reported as *en route* for delivery a year ago proved so defective that it had to be rejected. The manufacturers are still confident, however, that they can meet the requirements, and it is hoped that through the collaboration of Prof. Ritchey, of the observatory staff, who has spent some months at St. Gobain during the year, a satisfactory disc may be ultimately secured.

The field-work of the terrestrial magnetism department has gone forward with dispatch. Surveys have been carried on in fifteen different countries distributed over four different continents. The routes traversed by the observers will give a large aggregate of data from hitherto little-known or unexplored regions. Thus Mr. Sowers has obtained observations at intervals along a route extending from eastern China west across China and Chinese Turkestan, and thence south to Bombay, India; Prof. Beattie, research associate of the department, has completed a survey from Cape Town to Cairo; Mr. Pearson has secured measurements in Persia, Beluchistan, Arabia, Turkey, and Russia; while other observers have been equally active in South America, Central America, and British America.

The publication of sixteen volumes of researches has been authorised by the executive committee during the year at an aggregate estimated cost of \$5401.

RECENT WORK OF GEOLOGICAL SURVEYS.¹

III.—CANADA.

THE Geological Survey Branch of the Canadian Department of Mines continues to issue colour-printed geological maps at an extremely moderate price, as well as numerous mining plans on a large scale. We note that "individual maps or reports will be furnished free to bona fide Canadian applicants."

The Mines branch deals in its reports with technical matters relating to ore-deposits, the occurrence of which means so much to the Dominion; but its memoirs cannot be neglected by the geologist. Mr. Fritz Cirkel's report on the chrome iron ore deposits in eastern Quebec (1909) thus contains an interesting account of the serpentines of Canada (p. 12); the chromite occurs in those of Cambrian age, while the earlier serpentines appear, so far, unproductive. The Cambrian serpentines are associated with diorite, and are regarded (p. 13) as alteration-products of an olivine-gabbro. Their non-aluminous character, as shown in the typical analysis given, would lead one to assume that considerable differentiation had gone on in the basic series, and that the serpentine was at one time an olivine rock rather than a gabbro. This is probably the author's view, as stated on p. 87. The chromite is irregularly distributed in pockets, a provoking arrangement for the miner, and reminding one of the occurrences in the Dun Mountain district of New Zealand. This report, with its review of chromite ores in the world at large, is of far more than local value, and the deposits in the Transvaal, so recently described, are well referred to and illustrated. Mr. F. Hille's report, on some iron-ore deposits in Thunder Bay and Rainy River districts, Ontario, dwells on the possibility of using peat-coke, manufactured by the Ziegler process, as a fuel for smelting. Many provinces of Canada are rich in peat, poor in wood, and destitute of coal. The ores dealt with in the report are magnetite and hæmatite, and a magnetic survey has been used in the detection of the former.

The recent reports of the Canadian Geological Survey Branch include one by Mr. W. H. Collins on Gowganda Mining Division, Ontario (1909), with a very large geological map on the scale of one inch to one mile. The district described lies along the Montreal River, west of the Quebec border, and is being invaded by a rush of prospectors, owing to the discovery of silver cobalt ores similar to those that have made the reputation of Cobalt. The valuable veins occupy large fissures in quartz-diorite, which is intrusive in Huronian sediments. The author traces a magmatic gradation from the diorite into an aplite intimately associated with it (p. 33). The illustra-

¹ The second article appeared in NATURE of February 10.

tions show well the physical characters of this forest-clad region, which, with its lakes, rivers, and low hills, is, indeed, typical of the pre-Cambrian lands of North America.

Mr. Collins also reports on the "Region lying North of Lake Superior between the Pic and Nipigon Rivers, Ontario" (1909), where he was again on the great Archæan peneplain. The soils, still so deficient on this recently glaciated surface, fill the river-valleys and depressions, and "form a thin, discontinuous blanket that ineffectually covers the underlying Archæan floor." Mr. W. J. Wilson's report on parts of Algoma and Thunder Bay districts, Ontario, is bound up with that by Mr. Collins, and covers the river-courses of the country to the north and east. The large map illustrating both papers, on the scale of eight miles to one inch, together with the photographic illustrations, shows how exploration must for a long time be confined to the natural channels through the woodlands. Fossiliferous beds of Silurian age have been found on the tributaries running from the south and west into the Albany River. Their fauna is described by Mr. Whiteaves in an appendix (p. 34), and the report, with characteristic Canadian foresight, also illustrates the modern fauna in the form of speckled trout and store-clad Indians.

Mr. O. E. Leroy writes on the "Main Coast of British Columbia and Adjacent Islands in New Westminster and Nanaimo Districts" (1908), where he has a fascinating field among the fjords north-west of Vancouver. The drainage-grooves now entered by the sea are believed to have originated in early Cretaceous times, when great erosion prevailed. The country has been modified by local glaciation and by the passage of the lobe of an ice-sheet down the Strait of Georgia, inside Vancouver Island. A great batholite, varying in composition from a granite to a gabbro, invaded the Palæozoic sediments and igneous series, probably in the Upper Jurassic epoch, and has left conspicuous traces of its gradual advance by "stoping" (p. 17). This mass is responsible for a large part of the steep and rocky scenery along the fjords. The country appears rich in lead and copper ores, and magnetite awaits further development on Texada Island. The coal on Vancouver Island and the limestone on Texada Island are suggested as local means of smelting.

Mr. D. D. Cairnes's report on part of the Conrad and Whitehorse mining districts (1908) gives impressive illustrations of the grim scenery of Yukon. Aërial tramways now bring up fuel and food to claims on Alpine ridges, and the telephone prevents the feeling of isolation which tends to grow on pioneers. Conrad City is so young that it does not appear on the contoured map constructed in 1906, but we understand it to be at the foot of the Montana tramway. A photograph of it, facing the huge mountain-wall across the lake, assures us of its reality. As usual, the best is made of everything, and we are told that the long summer days may be delightful, although the lake waters remain so cold as to threaten death to those immersed in them. The gold-mining is in vein-quartz traversing Palæozoic schists, as in the Klondike fields. The granite that is so conspicuous on the coast of British Columbia cuts these schists, and is overlain by porphyrites and the Lower Cretaceous Tutshi series. A post-glacial eruption (p. 37) of considerable magnitude has formed a layer of volcanic ash 3 to 6 inches thick over a wide area in the valley-floors.

The Canadian Survey is not entirely absorbed by the excitements of mining enterprise. Dr. D. P. Penhallow, in a handsome quarto, reports on the Tertiary plants of British Columbia. This includes a review of all the known species, conveniently arranged alphabetically under genera, which are also in alphabetical order. The basis of the present work is an extensive series of plant-remains collected by Mr. L. M. Lambe for the Survey in 1906. East of the Rocky Mountains, the Canadian lignites are of "Laramie" (Eocene) age, though they have been referred by Heer, as was his general practice, to the Miocene. Similarly, the "Miocene" lignites of British Columbia are shown, by Dr. Penhallow's analysis of species, to be partly of Laramie and largely of Oligocene age. Sir William Dawson's views have thus been verified in detail. The table on p. 152 will be useful to stratigraphers.

Part iv. of the third volume of "Contributions to Canadian

Palæontology" is by Mr. Lambe, on the Vertebrata of the Oligocene of the Cypress Hills, Saskatchewan. This is a continuation and revision of a previous work by Cop and describes several new species, including *Amia exilis* and *Lepidosteus longus* among fishes, represented by fragmental remains, a probable anthracotherian tooth, and the well-preserved lower jaw of a Titanotherium, *Megacerops primitivus*. Eight excellent plates, from the author's drawings, accompany the memoir.

G. A. J. C.

PAPERS ON AMERICAN INVERTEBRATA

NOS. 1706, 1710, 1712, and 1713 of the Proceedings of the U.S. National Museum are devoted to the descriptions of various groups of invertebrates from American territory. In No. 1713 Mr. S. S. Berry deals with a series of new cephalopods from the Hawaiian Islands, among which special interest attaches to the new genus and species *Stephanoteuthis hawaiiensis*, an apparent member of the Sepiolidae, characterised by the peculiar shape of the body and the ventral anterior extension of the mantle to cover the funnel. In other respects the genus is, however, related to *Heteroteuthis*. A remarkable globular form, described as *Cranchia globula*, is related to *C. reinhardti*, in which globularity appears to be a feature of immaturity, but whether the same holds good for the new form—in which, indeed, it is really distinct—remains for future determination.

Cœlenterates from Labrador and Newfoundland form the subject of No. 1706. These have been investigated by Mr. H. B. Bigelow, who finds that all of them belong to previously described species, so that their interest is largely geographical. Several of them have been hitherto known only from Greenland and northern Europe. The species *Catablema vesicaria* and *Aeginopsis laurentii* have, however, proved of interest from an anatomical point of view and are important in regard to the classification of the Narcomedusæ.

In No. 1710 Mr. E. B. Williamson revises the arrangement of the North American dragon-flies of the genus *Macromia*, from which he finds those described as *Epophthalmia* to be inseparable. *Didymops*, as regards venation, appears to come very close to *Macromia*, but may seemingly be distinguished by other characters. Two new species of the genus under review are named and described.

No. 1712 is devoted to the second part of Dr. N. Annandale's account of the fresh-water sponges in the collection of the U.S. National Museum, none of the few forms referred to being new to science.

EDUCATION IN ENGLAND AND ABROAD.
